

Glossing of descriptive terms, and how to read a grammar

Jinyuan Wu

August 25, 2022

1 Theoretical orientation

1.1 The surface-based approach

1.1.1 Frameworks

The contemporary generative syntax is usually in a lexical-decomposition manner: that is, sub-word and even sub-morpheme features are the basic units of morphosyntactic operations. The features are fed into Merge to construct a binary tree with possible multi-domains (or a binary tree with chains recording copying or Internal Merge), and then the tree is linearized and post-syntactic operations are applied so features are assembled together to form words. This approach is not appropriate for language description, the latter requiring a more surface-oriented approach.

There have already been several relatively stable descriptive frameworks. Modern descriptive grammars of underdocumented languages are usually carried out within the framework of Basic Linguistic Theory (BLT), which is theorized in Dixon (2009, 2010, 2012), and, according to Dixon, deviates striking from the bond-to-fail generative approach. The BLT approach assumes no fine-grained constituency hierarchy, represents dependency relations not by constituency structure, and views constituent order as mostly driven by pragmatic reasons. In a word, BLT is the lay version of functional syntax à la Simon Dik.

On the other hand, already well-known languages are often described in the framework proposed in The Cambridge Grammar of the English Language (CGEL) (Huddleston and Pullum, 2002). This framework is also taken in Abeillé and Godard (2021); Huang and Shi (2016), and its varieties are used in Demonte (1999); Muñoz et al. (2000); Bosque (1999). The CGEL approach is more informed by generative syntax: it maintains a largely binary-branching analysis, and dependency relations are still highly bounded to the surface-oriented constituency tree, though certain dependency relations that involve movements that are hard to find by looking at the surface form require special treatment: and thus the subject in a clause is recognized as a complement of the verb, but since it is outside the verb phrase (VP) and the A-movement to SpecTP is not recognizable in a surface-oriented, a new syntactic function label *external complement* – essentially a way to represent a dependency relation – is invented to cover the relation between the subject and the verb. In a word, the CGEL approach is the surface-oriented version of the mutual consensus of Minimalism (and GB) and HPSG.

Though the BLT approach, and the contemporary generative approach, or the Minimalist one, differ in several important aspects, the two frameworks roughly describe the same grammatical complexity class: I will show this in the rest of this note. For abstract discussion, see chap. ?? in my notes about Chinese syntax. The take-home message is CGEL may be viewed as the surface-oriented dual theory of the constituency structure of Minimalism, while BLT may be viewed as the surface-oriented dual theory of the dependency-based formalism of Minimalism. The relation between the three is visualized in Fig. 1.

In the literature, the constituency-based approach is frequently called the *structuralist* one, while the dependency-based approach is frequently called the *functionalist* one. The latter doesn't necessarily look like more theoretical 'functionalist' approaches, like the Systematic Functional Grammar. We see both extremes aren't suitable for surface-oriented analysis: the surface-oriented constituent tree is not enough and additional function labels like *subject* and *internal complement* are required, while the surface-oriented dependency tree can't reveal what commonly attributed to constituency relations, like extraction properties. The CGEL approach is closer to the so-called structuralist approach,¹ and the BLT approach is closer to the so-called functionalist

¹Actually, there is no wide gap between the old-fashioned structuralist approach and the modern CGEL approach: if we look closer to structuralist grammars in the age of Bloomfield, e.g. Chao (1965), we will still find primary function labels like *subject* and *predicate*. The main differences include function labels are sometimes

approach. We know there is no substantial divergence between the two. Indeed, people often say “modern typology is based on functionalist syntax” and “descriptive grammars used in typology are strongly influenced by structuralism à la Bloomfield” at the same time, and as we see, both claims are correct.

Note that it is frequent for comprehensive grammars about well-known languages to be carried out in term of BLT. Examples include [Batchelor and San José \(2010\)](#); [Batchelor and Chebli-Saadi \(2011\)](#). This is possibly because these languages fit in the framework of traditional grammar well, and since BLT may be regarded as “traditional grammar informed by theories”, that certain grammars of well-documented languages are BLT-like is expected.

Box 1.1: BLT in the generative community

Indeed, contrary to the prevalent idea in the so-called functional-typological community, there *are* generative linguists participating in language documentation and description, though in the generative community, the BLT approach is usually said to be simply *descriptive*, in contrast with *theoretical* works, i.e. generative works. Here is a list of some linguists participating in both descriptive and theoretical enterprises (as they call them) and their descriptive works:

- David Adger: [Adger \(1997\)](#); [Adger and Ramchand \(2006\)](#); [Harbour et al. \(2012\)](#).
- Chris Collins: [Collins and Honken \(2014\)](#); [Miller et al. \(2007\)](#), as well as videos with subtitles that can be found with a Google search.
- Daniel Harbour: [Watkins and Harbour \(2010\)](#), and his collaboration with David Adger.
- Roberta D’Alessandro: [Andriani et al. \(2022\)](#); [Frasson et al. \(2021\)](#).

There is no qualitative boundary between their “descriptive” and “theoretical” works: the descriptive part reveal grammatical categories, dependency relations, and constraints on constituent order demonstrating functional domains, and all these things are put together in the theoretical i.e. generative part. Their workflow differs from with functional-typologists only in how they deal with the output of the BLT part: the generative approach shows the construction in question is possible in the sense that it can be derived with processes observed before, while the typological approach measures how probable it is by comparing with other languages. These two approaches are in fact complementary and not contradictory.

1.1.2 Some caveats

Before going on, I need to list some caveats. The first is many terms in this note may be confusing in the context of generative syntax: I use the term *lexicon* in a more traditional way (§ 5.1.1), and use the term *semantic role* in place of *thematic role*. Sometimes, it’s said that language description would better be carried out in a semantic-first approach ([Dixon, 2005](#)). Here the notion of *semantics* is also not the same as semantics in formal semantics or cognitive grammar: it means things like the tendency between the semantic classification of verbs and its argument structure. Indeed, in the light verb theory in generative syntax, certain aspects of semantics are of course involved.

The second is about **gradience**. Generative linguists usually assume the I-language is discrete, while functionalists insist that they are by nature gradient. However, gradience in cognitive research is different from gradience in language description: for a population in which each person has a discrete (but not necessarily identical) grammar, then a sketch of the grammar of the group is gradient as an effective theory. And if the grammar of each person is gradient, discrete models – like those used in historical linguistics – are still quite useful. Therefore, in this note I will talk about “one construction is somehow between the two”, even if this makes

mixed with category labels i.e. form labels, for example in terms like *verb-object construction*, and argumentation in support of function labels (see § 2.5.3) is often in lieu. But using category labels in place of function labels sometimes is acceptable (§ 2.4.1), and argumentation may be omitted in the grammar (§ 2.5.1), so the differences are merely about writing styles rather than theoretical divergence.

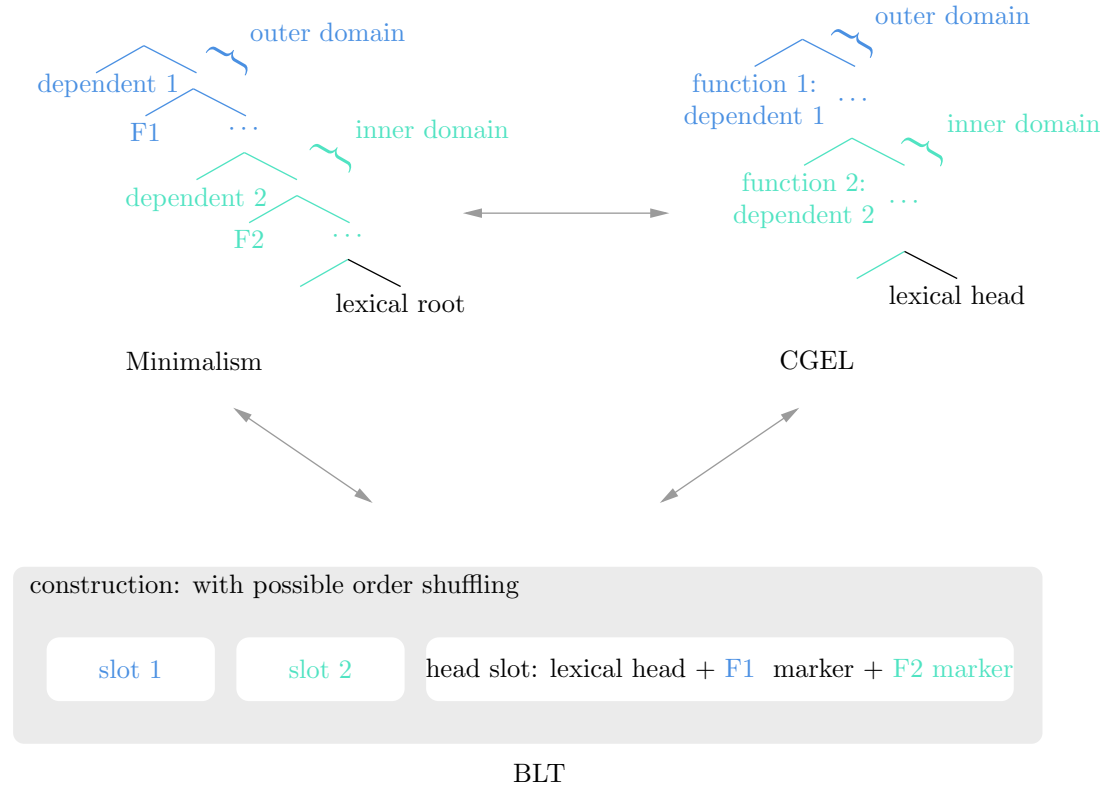

Figure 1: The generative formalism and two surface-oriented formalisms used in language description. The hierarchy information of the Minimalist formalism lost when deriving the surface-oriented formalisms is reminded by grammatical functions like *indirect complement* and *function fusion* in the CGEL formalism, and by grammatical dependency relations like “slot 1 is the syntactic topic” and “the dependency relation between the lexical head and the F1 slot is coded by the F1 marker” in the BLT formalism.

no sense in the corresponding theory. I may talk about a word being both a lexical word or a function word, though in Distributed Morphology, the first originates from the root of a functional hierarchy, and the first originates from span spellout of a functional hierarchy. The two mechanisms are in conflict with each other, but it's obviously possible for a person to have competing grammars in his or her mind, and for a population to have competing – but still largely mutually understandable – grammars. The gradient description is therefore acceptable as a first approximation.

The third is language description itself doesn't make claims on the cognitive nature of languages – but the theory framework used may be of cognitive significance. Tree-adjoining grammar (TAG), for example, has been used in psycholinguistic researches. But when a constituency tree-based approach or a dependency tree-based approach is picked up, the linguist usually doesn't think too much about its cognitive foundation, though there are almost certain aspects in which it does hint something about cognition.

A final remark is the term *language description* itself. Some people use the term *language documentation* to denote the activity to gather as much as original data (they should be roughly annotated, but the most important point is to record data as they are, avoiding never details). The term *language description* means the activity happening after language documentation, i.e. surface-oriented analysis, grammar writing, and typological research. This note is mainly about the latter, not the former. Accumulating texts requires

1.2 Questions to ask about the underlying theory

Beside the discrepancy between the BLT and the CGEL approaches, there are still further divergences within the BLT approach. So here I list some dimensions of divergence.

1.2.1 Pre-compiled phrasal templates

Is the theory purely lexicalist, or are there syntactic templates?² Though in a quick glance, it seems the lexicalist approach agrees with the Minimalist syntax while the templatic approach agrees with the constructionism, things aren't that simple: remember, a Minimalist syntax runs on features which aren't directly visible, and words and morphemes are just quirky reflections of them. The corresponding surface-oriented version of a Minimalist syntax with lots of features that are used to guide the syntactic derivation (e.g. the EPP feature), then, inevitably contains syntactic templates that are hard to place under any lexicon entry. The Cinque hierarchy of clause structure, for example, contains tons of invisible functional heads, and once we “integrate out” these functional heads, the resulting grammar has a clause template. The linguist has to consider whether to introduce a chapter named “the structure of noun phrases” or a chapter named “the clausal structure”.

1.2.2 The morphology model

How is morphology dealt? This parameter has strong association with the previous parameter, since there is no clear distinction between a morpheme and a word. In morphology the lexicalist extreme is the Item-and-Arrangement approach, while the templatic extreme is the Word-and-Paradigm approach. The Item-and-Process approach is somehow in the middle, maybe in a position closer to the former and further from the latter. What brings in more complexity in morphology is there are post-syntactic operations: even when the features do spellout into morphemes, the Distributed Morphology-style post-syntactic operations blur the correspondence between features and morphemes, and hence the idea that words are built up by morphemes doesn't lead to any constraints on the form of the word, raising doubts about whether in a surface-oriented analysis, morphemes are of any theoretical significance at all (Anderson, 2017). The linguist needs to pick up a specific way to show how words are built up.

²Sometimes the term *lexicalist* means the syntax works on words and not sub-word units. This is not the meaning intended here. The meaning intended here by *lexicalist* is “all grammatical rules can be reduced to how to use certain lexicon entries (lexical or functional)”, which may be words or morphemes or features. In other words, a lexicalist theory has no or few “global” phrase structure rules, as opposed to early generative grammars. This usage of the term *lexicalist* is attested in Matchin and Hickok (2020).

1.2.3 Where to find grammatical relations

How are grammatical relations (in other words, dependency relations) introduced? Together with morphemes that bear them, or words, or constituents, or with separate chapters and sections? This parameter has certain correlation with the top-down/bottom-up parameter, because in a top-down analysis, the grammatical functions of constituents in a larger construction are obviously introduced before what fill the constituent slots are discussed. On the other hand, a bottom-up grammar tends to introduce grammatical relations when discussing the smallest unit that bear them, for example talking about the case marking of various complements in the noun morphology chapter.

1.2.4 Notion of head, complement and modifier

What is the relation between a phrase and words contained in it? What is the head? What are the complements? What are the modifiers? In Minimalist syntax, all functional categories serve as heads, but lexical categories are never heads. This may appear strange but has underlying consistency (see § ?? in [my notes about Chinese syntax](#)). This approach, however, is not acceptable for a surface-oriented grammar, and here another concept – what determines the “overall” property of a constituent – is accepted as the standard to decide what is the head. Thus a *n*P and a DP are all headed by the central noun in the surface-oriented analysis, because both of them are built surrounding the core noun stem, and since the core noun stem is phonetically realized as the central noun – a lexical word – the latter is recognized as the head. Disagreements then arise when whether a word is functional or lexical is not that certain. Should the preposition be considered as a head? The preposition in a peripheral argument may be seen as the marker of a syntactic case system (so in the generative analysis, we have PP and CaseP), and under this analysis, the preposition is not a head. But in many languages like English, the preposition category has certain predicative properties, making it appear like a lexical category, and then it seems an noun phrase (NP) with a preposition is no longer an NP – it is a preposition phrase (PP) headed by the preposition.

1.2.5 Constituent levels

Are there fine-grained constituency structures, or are there just noun phrases and clauses? Some grammars, like the CGEL, posits an anatomy of NPs with the following functional domains: head noun – nominal – minimal NP with a determiner – external modifiers. Others just list possible NP dependents or clausal dependents, without discussing which is closer to the head. If the latter approach is taken, the linguist has to introduce effects due to the relative position of constituents in another way, like “the O argument in ergative languages is more topic-like”. The main reason to take the latter approach – which is the approach advocated in BLT – is only NPs and clauses have complete semantic significance. See BLT § 1.11, (33) and (34): Dixon doesn’t like the binary-branching (Minimalist) approach (33), because it doesn’t illustrate the fact that the function words are different from lexical ones. But this is more a problem of terminology: the term *phrase* in BLT corresponds to a maximal domain like DP or CP in generative syntax, while a generative *phrase* – like *v*P or AdvMannerP – corresponds to a grammatical construction in BLT.

1.2.6 The syntax-morphology distinction

Whether to adopt a clear distinction between syntax and morphology.³ From a Distributed Morphology perspective, the only distinction between what is traditionally regarded as syntax and what is traditionally regarded as morphology is that the latter involves more post-syntactic operations. Once these operations are undone, CGEL and BLT analysis for syntax is applicable to the morphemes (or grammatical categories in the Word-and-Paradigm approach): the lexical stem of a word may be regarded as with no definite category, and hence lexical category labels are in essence function labels (Fig. 2).

³This parameter involves the term *lexicalist* in another sense (compare footnote 1.2.1). If there is a clear distinction between syntax and morphology, i.e. there is a stable notion of *word*, then the theory is *lexicalist*.

Figure 2: The lexical category *noun* as a function label: in a generative grammar, a nP (nominalizer phrase) is placed in a functional projection FP, and a noun stem is placed as the complement of the nominalizer. After coarse-graining the generative syntax tree and using function labels to replace functional heads, the F functional head in the FP projection is replaced by the F label on the right side. Then, by the same logic, the nominalizer should be coarse-grained into a “Noun-stem” function label, and the nP projection is coarse-grained into the “Noun” category label. In practice, the orange box on the right side is contracted into one single word, i.e. the noun, and thus we can see the category label of a word also has a hidden function label inside.

1.2.7 Constituent order

How is constituent order (often called *word order*) introduced? Is there a separate chapter devoted to constituent order? Constituent order can be understood as a manifestation of constituent hierarchy, while in more functionalist approaches, it is understood as a method parallel to morphological marking that marks the constituent positions in a larger construction. Note that the second claim doesn’t go against the first one: certain features, e.g. EPP, are indeed reflected by the surface constituent order in generative syntax. Languages may also have macroparameters directing how to linearize generative syntactic trees, which doesn’t involve features (which are syntactic objects) and are rules on the interface between PF and the syntax proper. Indeed, there are linguists claiming that constituent order is merely morphology and should not be taken too seriously when discussing the syntax proper.⁴ Certain mechanisms that do not involve features (e.g. Antisymmetry) can’t be translated transparently back into the second approach, though, but they can be framed in the second approach as “the human language faculty just rejects certain constituent orders anyway”.⁵

1.2.8 The notion of canonical constructions and transformation rules

Whether a set of canonical constructions is established. Viewing non-canonical constructions as transformed from canonical ones (or by adjunction, etc.) is a powerful descriptive tool, but it is often the case that certain constructions that are uncontroversially deemed non-canonical do not have a canonical counterpart. This is one of the reason transformational rules are finally abandoned in generative syntax. Transformational rules (and adjunction, etc.) are still handy when doing description, though: no one wants to read a grammar that treats positive clauses and negative clause in the same way.

Both BLT and CGEL have strong tendencies in the values of some (though not all) parameters listed above. The parameters that are largely fixed by the overall descriptive framework include whether fine-grained constituency hierarchies appear, how is constituent order introduced, and the definition of *head*. It is of course possible to mix the BLT and the CGEL approaches:

⁴In BLT, Dixon says constituency order is a way to mark constituents’ function label and is of secondary interest. He contrasts this with the approach taken by “formalists”, who allegedly want to use an English-informed framework to catch all things of a largely unknown language. The point here is Dixon’s approach *is* in fact the approach taken by formalists in the real world.

⁵One controversy here is the generative feature-driven constituent order often involves movement, while functionalists accept constituent order variations “as they are”. This controversy is false, because for many generative linguists, movements can be unmarked, and what movement means is simply dual syntactic function of a constituent or the imperfect relation between constituent order and dependency relations (e.g. cross-serial dependencies).

Friesen (2017), for example, despite being a largely BLT-like grammar, uses the term *verb phrase* in the way of CGEL, while the parts about NPs are typically BLT-like. On the other hand, Muñoz et al. (2000), despite its employment of CGEL-like terms, doesn't emphasize on tree diagrams and constituency structure, nor its possible constraints on the constituent order, and is much more BLT-like than the CGEL itself or the great French grammar (Abeillé and Godard, 2021). Another example of mixing of the CGEL approach and the BLT approach can be found in CGEL itself: ditransitive clauses can be analyzed in Minimalism, but the analysis inevitably involves lots of movements to make the dependency relations correct, so CGEL just gives up binary branching in exchange of a much clearer surface-oriented analysis, where the syntactic properties of the direct and indirect objects (two grammatical functions not found in monotransitive clauses) are manually stipulated. This is just how BLT works when the constituency relations are complicated.

Choosing between the approaches in CGEL and BLT and the rest of the parameters are to be decided by the grammarian, and some best practices are introduced in § 2. In principle, the above parameters are free to choose. In practice, they have to be fine-tuned or otherwise the grammar will be hard to read.

2 Common practices of grammar writing

2.1 What influences the organization of the grammar

Parameters in § 1 have to be fine-tuned according to the following factors:

- The properties of the language. If a linguist unfortunately decides to write a Chinese grammar in a bottom-up manner in which a grammatical relation is introduced in the chapter about the lexical category about its head, a reader will soon be stuck in questions like what are the possible linear order between object(s), directional complement, and aspectual markers. On the other hand, it is okay – and even desirable to write a Latin grammar in this way, because Latin is much more free-order than Chinese and grammatical relations are mostly marked by morphology.
- Whether the language is already well-known. In § 1 we have already seen that comprehensive grammars of well-known European languages are usually CGEL-like, while newly documented languages are usually captured by BLT-like grammars. This is again expected, because in-depth partition of constituents is never the priority when describing a newly encountered language.

It should be noticed that what is in the final version of the grammar has no absolute relation to what is done to reveal the grammar. A chapter in a grammar about verb morphology may list all attested Tense, Aspect, Mood, Evidentiality (TAME) categories marked on the verb, and then show morphemes corresponding to these categories, while the workflow to investigate the paradigm is likely to be carried out in reverse order: grammarians often first record all attested forms of a verb, and then try to find the morphemes, and finally link them to TAME categories. The morphemes attested, actually, are the strongest evidences for or against certain analyses of what TAME categories are coded. This explains why many authors love the bottom-up approach. But again, they inevitably need some top-down partition: at least they have to be able to identify NPs and clauses! These scaffolds are removed once the building of the grammar is finished. They may still leave traces in the finished work: This is the topic I am going to discuss in § 2.5.

2.2 Introductory chapters

2.2.1 The introduction chapter

In modern grammars, the first chapter of a grammar is usually about its genetic affiliation, its population, geographic and cultural information, typological significance, and similar topics. Grammars focusing on raw fieldwork data may also list available texts and corpora.

2.2.2 The grammar sketch

It is common – but not necessary, counterexamples including Grimm (2021) – to have a grammar sketch chapter then. This brings some (though not all, for reasons below) benefits of the top-down approach to a grammar that is not carried out strictly in the top-down manner, and thus makes it easier both for readers to understand the language and for the author to describe what he or she knows. In many grammars, though, the grammar sketch chapter is just the zipped version of the following chapters organized in a bottom-up manner instead of something like § 3, and readers in a hurry – possibly readers who want to know what syntactic categories are marked in the clause, or readers reading a grammar to give a construction a generative analysis – are unlikely to find what they want in the chapter without reading it from the beginning to the end. They should not expect what they need is fully summarized in a single section.

Take Jacques (2021) as an example. The morphosyntactic part of chap. 2 is thoroughly bottom-up, with attested lexical categories being introduced first, then nominal morphology, then verbal morphology, then argument indexation and flagging, and finally constituent order and subordination. Readers need to dive deep into § 2.4.3.2 to see what TAME categories are marked in the clause – since they are marked on the verb complex and the author writes the grammar in a bottom-up way, introducing grammatical categories in the sections about smallest constructions that manifest them, a comprehensive list of TAME categories can only be found in a small corner in the section about verbal morphology.

There is one particular benefit of having a grammar sketch chapter. A grammar needs argumentation to support a function label. When the author says “the subject is available for more extractions than internal complements”, the readers are expected to know where these movements happen, which, unfortunately, are usually introduced after the concept *subject* appears, in the chapter about information structure. Having a grammar sketch means non-canonical constructions can be used to support a particular analysis of a canonical construction.

Another benefit of the grammar sketch chapter is necessary top-down information can be collected there. If you really want, you can first enumerate all grammatical categories in a clause and then introduce each of them. In practice, finding all grammatical categories can be done by looking at the name of each section, so this probably is not necessary.

2.2.3 Phonetics and phonology

The following chapter(s), if any, is usually about phonetics and phonology, and possibly about the preferred writing system. This chapter may be omitted for languages already well known, like English. There is no phonology chapter in CGEL, for example. This note is not about phonology, so I will just skip this part. It should be noted that readers interested in a largely unknown language would better know something about the phonology, even if their primary interest is about morphosyntax, because phonological rules can blur otherwise clear constructions.

What happens next observes more variations. In the following I discuss frequent strategies to arrange chapters about morphosyntax. These strategies aren’t mutually contradictory: good grammars mix them to meet the need in § 2.1.

2.3 Order of chapters

2.3.1 Top-down or bottom-up

Top-down (i.e. structuralist partition-based), or bottom-up (i.e. based on the usage of smaller units)? In PSGs there is a clear correspondence between the two, but for actual language description things are often complicated: a top-down grammar is awkward to write because the author has to enumerate all possible configurations in a construction to fully characterize it (“a clause is either coordination of clauses or a subject-predicate construction” – oh no, supplementation and pre-nucleus constructions are forgotten), while a bottom-up grammar is awkward to read because the reader has to infer all possible configurations in a construction (“the verb is the prototypical content of the predicate slot” – any other possibilities? Nobody knows). This parameter is in principle orthogonal to the parameter about how constituent order is introduced, but a bottom-up grammar without a chapter (or several chapters) devoted to constituent order will be extremely hard to read: the reader may find a sentence like “the object

follows the verb” in the chapter about verbs. Alright, can an adverb intervenes between the verb and the object? No answer.

A bottom-up grammar is about item and arrangement. A top-down grammar is about anatomy. It is possible to mix the two approach. For example, there may first be several chapters about morphology, and then syntax is discussed, so the morphology-to-syntax narrative order is bottom-up, but in the syntax part, first the subject-predicate relation is discussed and then the inner structure of the predicate, so the inner structure of the syntax part is top-down.

2.3.2 The NP-clause division

Some grammars can be divided into two parts: one is about NPs, the other clauses. Since BLT tolerates using names of lexical categories in place of the naming of their prototypical functions, sometimes we say these grammars are divided into a part about nouns and a part about verbs. Other grammars mix the noun chapters and the verb chapters together.

2.3.3 From canonical constructions to non-canonical ones

If two constructions are of the same type, but one is much simpler than the other, whether to place the simpler version together with the less simple version, or to place the simpler construction with other relatively simple constructions. Examples include whether the serial verb construction should be discussed together with the simple verb-complement construction – the alternative arrangement is to place the verb-complement construction together with alignment and argument indexation in a chapter named, say, “simple clauses” – and whether the relative clause construction should be introduced in the chapter about NP dependents, or in the chapter about clause types, or in a separate chapter. This chapter is related to the parameter about canonical constructions: NPs without relative clauses may be viewed as canonical NPs, and non-canonical NPs containing relative clauses can be obtained by substituting attributive modifiers with relative clauses.

2.4 Terminology

2.4.1 Form-based grammatical relation terms

Some people tend to use the lexical or phrasal category that prototypically fills a grammatical function slot as the name of that grammatical function. Here is a list of relevant terms:

- *Nominal* and *verbal*: the exact meanings of the terms vary from person to person.
- *Adverbial*, which is actually peripheral argument (Box 3.1).
- *Serial verb construction*, which is actually serial predicator construction.
- *Verb complex*, which is actually predicate (in the BLT sense) or the predicate minus complements (in the CGEL sense).

BLT-oriented grammars tend to use more form-based terms about function, possibly because these grammars are usually results of language description projects, in which linguists do not have much time to decide which is the best analysis of a phenomenon, and a large corpus with at least some annotation – despite possible quirks – is better than a few grammaticality judgement tests.

Confusing terms about form and function in practice does *not* cause much problems – see § ?? in [my notes about Latin](#).

2.5 Argumentation

2.5.1 The amount and position of linguistic argumentation

This section is about how to make linguistic analysis and argumentation, and how it is shown in a grammar. A grammar without argumentation will be confusing: readers will ask “why does the author say there is clear distinction between nouns and verbs”, and the answer can only be found by comparing the distribution of nouns and verbs by themselves. To a certain extent,

a grammar without enough argumentation is not truly finished. It is just an *legend* about the “shape” of a language, and all the reader need to do is to accept the story as it is and never ask why.

A grammar with too much argumentation will be messy. Consider a grammar in which there are discussions both on how to do a top-down partition of a clause and on how to assemble verbs and NPs into a clause. It is often the case that the reader has to switch between the two parts frequently because a grammar point is introduced in one but a highly relevant grammar point can only be found in the other.

Even when the amount of argumentation is appropriate, where to place them is still quite an art. Argumentation for distinguishing ditransitive verbs and monotransitive verb with an extended argument, for example, may be carried out in a chapter mainly about canonical clauses, but it inevitably involves something about non-canonical constructions (passivization, extraction, etc.) which are still largely unknown for readers reading the grammar from the beginning to the end. Adding a grammar sketch chapter may ease the problem (§ 2.2.2).

Sometimes argumentation is mixed with description. It is possible to talk about what argument can be passivized in the chapter about clausal dependents in canonical clauses, and then shun the topic in the actual chapter about passivization. This makes the grammar concise but also harder to read, because readers interested in passivization will then have to switching between the two chapters.

2.5.2 Constituency partition

In BLT, the constituency relations are relatively simple, because there are only two basic types of constituents: NPs and clauses, while in the CGEL approach, the constituency relations are much more complicated (see Box 3.2).

2.5.3 Identifying function labels and dependency relations

The importance of function labels and dependency relations is exemplified well in § 3.1.4, and there is no need to repeat here.

2.5.4 Distinguishing lexical and phrasal categories

Lexical and phrasal categories can be classified by their internal makeup as well as their external distribution. Similarly to argumentation about function labels, if a category label is established, then certain implicational rules about the category exist in the grammar. The claim that “Latin verbs conjugate, not decline, and they head clauses” can be equivalently formulated without mentioning *verb* as “if the inflectional endings of a word attested fit in the so-called conjugation table, not the declension table, then it is likely that the word prototypically appears in the predicator position of clauses”.

2.6 Corpus data

2.6.1 Deeply annotated or shallowly annotated

How corpus examples are given – fully bracketed and labeled, or represented as is? In the first case, an example is a demonstration of the grammatical *rules* generalized in the grammar, while in the second case, an example is just there as a piece of observation. In practice, no reference grammar is truly generative in the sense of listing all permitted forms and excluding ungrammatical forms. Thus, examples are never presented purely as examples of grammatical rules. But whether they are “deeply” or “shallowly” annotated still observes lots of variations. This parameter has relation with the top-down or bottom-up parameter, but the relation is not absolute: in general, the more bottom-up a grammar is, the more observation-based it is, i.e. the examples are provided as is without much tree diagrams or bracketing expressions. But it is of course possible to have a top-down grammar which doesn’t make much generalization about grammatical rules that generate grammatical utterances and exclude ungrammatical ones. Indeed, this is exact the case for the structuralist Immediate Constituent Analysis: partition of corpus data is made, but there is no generalization about what is permitted and what is not. The correlation between the bottom-up narrative order and the observation-based approach is likely due to it is the easiest way to document something about a language without mistakes.

2.6.2 Full or segmental utterance

Another parameter about how to give examples: as a bracketed constituent in a full utterance, or taken out of the context? Structuralist works, like [Chao \(1965\)](#), tend to employ the latter approach, while modern grammars are the opposite. Despite being concise and easy to formalize, the first approach is not easy to use (for obvious reason) and not easy to update: since the scaffolds of the generalizations are removed once the structuralist work is finished, readers are unable to find why the author decided to take a particular analysis when he or she was writing the grammar, and just like all (semi-)formalized theories, changing one rule may cause unexpected overgeneralization.

2.7 Workflow

It is now time to summarize the basic workflow to carry out a grammar. Though most modern grammars are bottom-up (just like their traditional antecedents), top-down constituency and dependency analysis of clauses is still important and is likely to be the first step in understanding the language. A toy example can be found in § 2 in [this exercise](#).

§ 3 summarizes how to do top-down analysis. Details of constructions that may be met aren't discussed in the section. They are discussed in the bottom-up sections after § 3. The organization of sections below implies our workflow: to first give a sketch of the language (where top-down analyses are important), and then dive in the details (and carry out the grammar in a bottom-up way).

3 Top-down analysis of syntax

Even for a largely bottom-up grammar, top-down analyses are sometimes necessary, both as scaffolds or as argumentation, which is discussed at the end of § 2.1. In this section, I discuss what to expect when analyzing and annotating clauses.

3.1 A sketch of the constituency tree of clauses

This section starts with a purely form-based analysis of clause structure. That is to say, distinction between grammatical labels like “subject” or “topic” is not touched. We first show possible syntactic devices – in other words, constituent analysis and “movements” – and then discuss what grammatical categories are marked by these devices, or in other words, how to assign function labels like “subject” and “predicator” to the nodes of the constituency tree obtained.

3.1.1 A clause is built up by one or more nuclei with certain syntactic processes

The top-level partition of a clause is given as the follows:

- (1) A clause is
 - the coordination of two clauses (§ 14.1), which may involve ellipsis in and/or movement out of the conjuncts, or
 - a clause with supplementation (§ 15), or
 - a clause without the two.
- (2) A clause without coordination or supplementation is
 - a clause with pre- or post-nucleus constructions (the residue of the nucleus clause undergoing relevant syntactic processes is named the **nucleus**), like the English subject-auxiliary verb inversion or *wh*-movement, or
 - a nucleus clause (see (3)).

Note that the distinction between coordination and adjunct clause construction (a type of subordination) may be not so clear for some languages, for example Latin (see [my notes about Latin](#), § ??). Also, there is no strict application order between coordination, supplementation, and pre- and post-nucleus constructions: in the English question *on that particular day – I mean the day when the unfortunate incident happened – did you pass that site or hear anything usual*

in that direction, first a coordination construction is used, followed by a subject-auxiliary verb inversion (a pre-nucleus construction) and then supplementation and finally another pre-nucleus construction (topicalization of the time adjunct). Another remark here is the syntactic processes from nucleus clauses to more complicated ones may only work for certain inputs: in English, for example, the supplementation *not even ...* is only possible for a clause in negative voice. A final remark is that finding the boundary of the nucleus requires testing the transformational properties of each clausal dependents. The constituency tree obtained by immediate constituent analysis is without labels, and it is impossible to decide, say, whether a constituent is a topic (a prenucleus construction) or a subject (a dependent within the nucleus). This fact leads some Chinese grammarians to abandon the distinction between topic and subject. Here is not the best space to have in-depth discussion for the definition of the nucleus. A working definition is given in § 3.1.2, but it involves terms like *complement* and *adjunct*, which can't be defined by the label-free constituency tree obtained by clause partition.

3.1.2 Clausal dependents in the nucleus

Now it is time to define the nucleus clause:

- (3) A **nucleus clause** is
 - a minimal nucleus clause, or
 - a nucleus clause with adjunction.
- (4) A **minimal nucleus clause** is a complex of
 - the **predicator**, prototypically a verb but with possible alternatives, possibly marked for grammatical categories involved in the clause structure, and
 - one or more visible or invisible **complements**, and
 - possible function words marking clausal grammatical categories
 or it is a serial verb construction (§ 3.4).

Here **adjunction** means adding **adjuncts** into the tree structure, in the manner in TAG. This is the surface-oriented counterpart of optional projections in Cinque hierarchies. Adjuncts are contrasted with complements, the latter being somehow closer to the predicator, but not necessarily obligatory. There are several tests to find whether something is a complement or an adjunct (see CGEL § 4.1.2, for example), but the distinction is usually quite blurred and language-specific (§ ?? in [my notes about Chinese syntax](#)). The complement-adjunct distinction is usually hard to test simply by pure constituent analysis, because an adjunct is not necessarily higher than all complements. The distinction is not what can be studied here – it has to be delayed to § 3.1.4.

The term *adjunct* used in this note means clausal modifier. *Adjunct*, in generative syntax, means optional non-head components of any projection, though nowadays, especially in the Syntactic Cartography program, it is often assumed that there is no adjoin operation beside the usual Merge, and so-called adjuncts are specifiers of certain optional functional heads, and hence the term *adjunct* loses its structural significance. Many descriptive grammars, like (Quirk, 2010), use the term *adverbial* for the term *adjunct*. A third name used for adjuncts are *peripheral argument* in BLT.

The term *complement* may sometimes be used to denote specifically *complement clauses*. In BLT, the term *complement* is usually replaced by *core arguments*. CGEL insists on a strict form-function distinction and hence the term *argument* is reserved for semantics. BLT, on the other hand, emphasizes on the semantic basis of syntax, and so the term *argument* is used. But here comes a subtle difference between BLT's standard of clausal dependents and CGEL's: certain constituents, like the direction complement in Mandarin Chinese (see § ?? in [my notes about Chinese syntax](#)), are definitely complements under the standard of CGEL, but are definitely not arguments, and hence they aren't recognized as clausal complements in BLT – they are thus recognized as a part of the BLT predicate (see Box 3.2).

3.1.3 Pre- and post-nucleus constructions not well defined for free-order languages

It should be noted that for languages with a relatively free constituent order, it is almost impossible to find a neutral order, and hence pre-nucleus and post-nucleus constructions can't

be well-defined, let alone the fact that some linguists posit so-called in-VP scrambling and the pronominal argument construction for radical non-configurational languages where argument NPs are actually adjuncts, which are by no means pre- or post-nucleus constructions but nonetheless induces changes in the constituent order. In this case, (2) and (3) should be merged together, and notions like pre- and post-nucleus constructions are to be replaced by discussions on the relation between constituent order and semantic and pragmatic information.

3.1.4 Classification of clausal dependents

In the above discussion I intentionally avoid mentioning subject and object or more generally, any complement and adjunct types, because as is discussed in the end of § 3.1.1 and in § 3.1.2, by staring at the surface form, it is impossible to define these terms. The constituent analysis of the surface syntax gives us a constituency tree without labels. In this section, I discuss how to add function labels to the nodes of the tree. The above discussion – why the surface-oriented constituency tree is not enough – has a strong flavor of CGEL. For BLT, the importance of function labels is much clearer: the complexity of the constituency tree is highly limited, so most of the information has to be conveyed in terms of dependency relations, i.e. function labels.

Trivially, the label of a node can be assigned as the category of the node. Thus we have [_S [_I]_{Pron} [_{VP} [_{like}]_V [_{fruits}]_{NP}]]. But of course *I* and *fruits* occupy different syntactic positions: from folk grammar we know the first is the subject while the second is the object. Can this distinction be seen from their structural positions? It is true that in generative syntax, complement positions can be distinguished purely in structural terms (SpecTP, SpecvP, etc.), but in the surface-oriented analysis the relevant functional heads are all invisible, and inevitably there are occasions when structural terms are occasionally insufficient to decide the role of a clausal dependent. A grammarian may want to define the *subject* as “the most external clausal dependent in immediate constituent analysis”, and this leads to the ridiculous conclusion that in *quietly, he entered the room*, the adverb *quietly* is the subject.

This example is a vivid example of the importance of *functional* labels in the constituency tree.⁶ Another illustration can be found in Fig. 1 in [my notes about CGEL](#): the information contained in the functional projections in the left tree is displayed in the functional labels like *predicator*, *agent*, *patient*, etc. in the right one. In the above example of the definition of the subject, “the most external clausal dependent in the nucleus” seems to work well. But *what* is the nucleus? This question is raised at the end of § 3.1 but has never been answered definitely. One may want to define it in semantic terms: “a nucleus clause contains all constituents that are necessary to complete the meaning of the verb”. But isn’t *quietly he entered the room* such a clause?

The conclusion is that in order to find complement positions, adjunct positions, the definition of *nucleus* – in a word, functional labels – in a language, syntactic tests based on transformational behaviors (or to be precise, based on comparison between regularly related constructions) is needed. The grammarian should expect lots of cross-linguistic variation of available functional labels, because they are reflections of the underlying feature structure, which allows plenty of variations. In a purported language without any EPP feature, SpecTP may not be of much significance, and hence the label *subject* – the combination of the syntactic agent i.e. the topmost argument in the argument structure, and the obligatory “topic” i.e. the topmost argument after TP is finished – is of little use. An example of how to find complement types is Fig. 11 in [my notes about CGEL](#). By six syntactic standards – constituent order, passivization, preposing, postposing, gap controlling, and predicative adjunct – five object-like complement types are identified, and four of them are recognized as objects with one being kicked out of the object family.

3.1.5 Alignment

Recognizing complement types is mostly about syntax. Semantics is also involved, of course, because otherwise it is impossible to decide whether one clause is transformed from another. But this is not what people already with knowledge on traditional grammar expect. What do semantic roles of complements and adjuncts do in complement type recognizing? They are

⁶Here *functional* means syntactic function and not pragmatic function.

important factors in determining complement and adjunct types, but they are by no means the decisive ones. Passivization is a well-known counterexample of the uniform matching between semantic roles and complement types. A locative role may be realized as a complement or an adjunct. The defective – yet still largely regular – mapping between semantic roles and complement or adjunct types is therefore worth separate treatment. This is what known as **alignment**.

Box 3.1: Nucluse clause and clausal dependents

Clauses can be constructed from nucleus clauses via pre- and post-nucleus constructions and/or coordination and supplementation. The nucleus clause contains clausal dependents and the verb complex. In the CGEL approach, the clausal dependents include complements and adjuncts. In the BLT approach, the clausal dependents include core arguments and peripheral arguments.

This note keeps all the four terms: *complement*, *adjunct*, *core argument*, *peripheral argument*. Though roughly complements correspond to core arguments, and adjuncts correspond to peripheral arguments, certain complements – like the non-argument complements in Chinese – are certainly not arguments, and may be included as parts of the BLT predicate (see Box 3.2). Adjuncts are also referred to as *adverbials* in some grammars. The complement-adjunct distinction and subclassification of the two types of clause dependents rely on syntactic analysis and argumentation based on extraction properties like preposing, valency changing properties like passivization, and marking of constituent order and morphology. Without syntactic argumentation, it is impossible to distinguish adjunct, complement, and topic (a pre-nucleus construction) or to find subtypes within clausal dependents, for immediate constituent analysis is unable to provide relevant information.

There is typically uniform but nontrivial mapping from semantic roles to complement and adjunct types, called alignment. Alignment can also be described as a mapping from the argument structure of a verb to the complement/adjunct types of arguments.

3.2 So-called “topics”

3.3 The inner structure of the verb-complement construction

3.3.1 The subject-predicate analysis

For languages in which *subject* can be well-defined (§ 6.2.1), it is useful to divide the nucleus clause into the subject and the predicate:

- (5) A nucleus clause is made up by an **external complement**, often named the **subject**, and a predicate.
- (6) A **predicate** is either a predicate without adjunction, which may be
 - a predicator-complement construction, or
 - a serial verb construction,
 or a predicate after adjunction, or a predicate after syntactic processes marking clausal grammatical categories like negation, modality, etc.
- (7) A predicator-complement construction consists of a **predicator** (which is the head of the predicate and the clause) and its **internal complements**.

The above rules replace (3) and (4). These are the rules used in CGEL, and actually also the Chinese school grammar (see § ?? in [my notes about Chinese syntax](#)). CGEL doesn’t acknowledge the role of verb complex, which is in principle correct, because English is already highly analytic and rigid-order, and most information about dependency relations can be reconstructed from the surface-oriented constituency analysis. Therefore, the term *predicate* is used as in traditional grammar: it means the nucleus minus the subject, and its status as a constituent summarizes § 6.2.1.

3.3.2 The flat-tree analysis of the verb-complement construction

It should be noted the above concept of *predicate* doesn't always correspond to an uncontroversially constituent in the surface structure: in a VSO language, for example, the predicate is discontinuous. This urges some to accept a flat-tree approach to describe the nucleus predicate.

To see another motivation of the flat-tree approach in surface-oriented description, consider the following facts. There are some controversies arising from the “what's the head” parameter in § 1.2.4. Some verbs are auxiliary verbs. In the clause *I should do this*, what is the predicator? Here we are in the same dilemma as the one concerning “preposition phrase”. An analysis in which the predicator is *should* will face the criticism that function words are never heads in a surface-oriented analysis, or otherwise, in order to be self-consistent, its bound morpheme counterparts should also be regarded as heads, which falls back to the generative functional head analysis.

The above two motivations urge us to take the analysis in which the main verb *do* is the predicator. This approach usually occurs with the flat-tree approach, or otherwise *should* is analyzed as a clausal dependent similar to the determiner in an NP, which is acceptable in the structuralist analysis of Chinese non-argument complements (see chap. ?? in [my notes about Chinese syntax](#)) but is not prevalent outside the Chinese grammar community. The nucleus minus arguments (core and peripheral) is named *verb phrase* in BLT, while in CGEL the term *verb phrase* means the verb plus its internal complements, which is the form of the predicate. The BLT *verb phrase* is the hierarchy *span* (as in *span spellout*, or the head slot in the BLT part in Fig. 1) of the CGEL VP shell. To avoid conflict, the term *verb complex* may be used to denote the verb phrase in the BLT sense (Hockett, 1948; Friesen, 2017; Wilbur, 2014). Now since there is no need to do fine grained partition of the nucleus, the term *predicate* can be assigned to something else and the commonly accepted practice is to use it to denote the verb complex. In this way, (5), (6), and (7) are replaced by the following:

- (8) A nucleus clause is made by a predicate (with a different meaning with the *predicate* in (6)) and core and peripheral arguments. Rearrangement of constituent order may be necessary.
- (9) A **predicate** may be a simple one or a serial verb construction (§ 3.4).
- (10) A simple predicate consists of a head (prototypically a lexical verb) and possible grammatical category markers (including auxiliary verbs).

This approach is not without doubt: the analysis that the main verb *do* is the main verb also faces a problem of non-consistency: the boundary between auxiliary verbs and lexical catenative verbs is somehow vague in some languages, and in this case, in somewhere in the grammaticalization process the head status suddenly flip from verb to another. Also, the problem of discontinuous constituent (the verb complex) still exists, which can also be seen from Fig. 1. But this is the practice accepted in BLT and most of grammars sticks to this paradigm, so I introduce it here.

3.3.3 Switching between the two

Finally I discuss how to translate between the two approaches. There are only two key points: in BLT, most heavy lifting jobs are done by dependency relations within a large, non-branchable constituent, not constituency relations, and what is a constituent depends heavily on semantics. Consider Fig. 3, which illustrates the divergences between CGEL and BLT over a simple predicator-complement construction. Here is a comparison between the two analyses:

- The argument positions in both approaches are labeled by explicit functional labels. The necessity has been argued in § 3.1.4: in Minimalism, the argument positions can be decided purely in terms of the structure: the subject is SpecTP, and object is SpecTransP, etc. But in the surface-oriented formalisms information contained in the constituent structure is not enough to tell us the role of arguments, and hence arguments are explicitly labeled via notions like “subject:”, “object:”, “subject slot” and “object slot”.
- The binding relation between the subject and the object is realized in BLT as “the subject tends to somehow control the object cross-linguistically”. This reflects the dependency relation-based nature of BLT: the fact that the subject is somehow “higher” than the

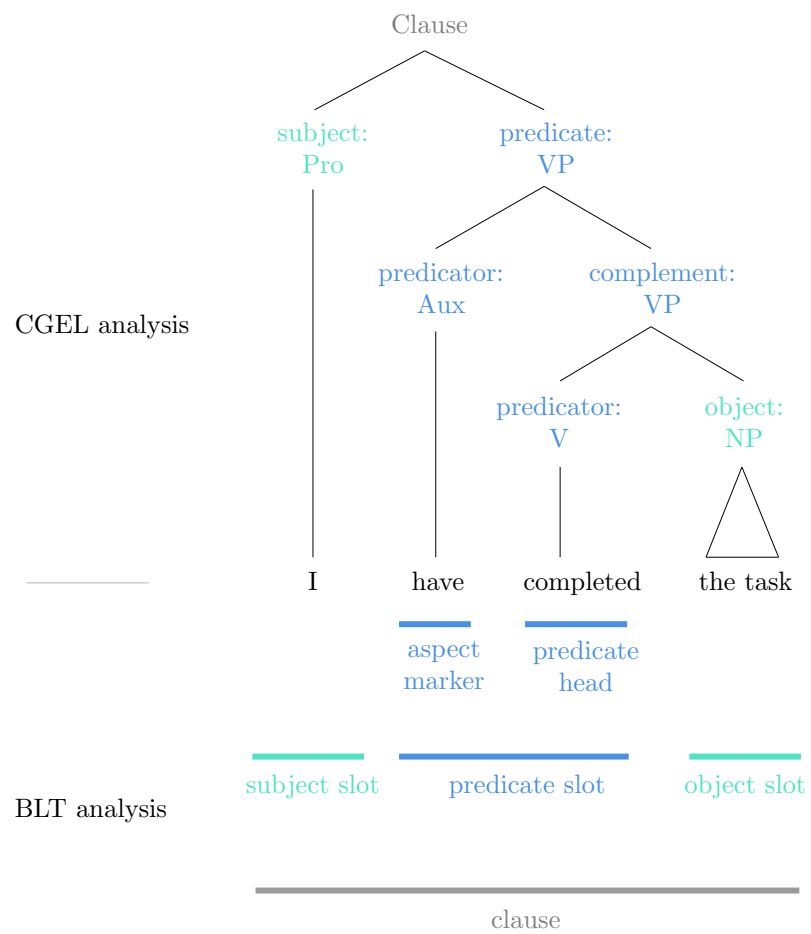

Figure 3: Comparison between a BLT analysis and a CGEL analysis

Figure 4: The structure of a simplest BLT predicate

object is not reflected in the constituent structure, but rather by a dependency relation placed in the clause template.

- The fact that *have completed* is a span in the TP projection is reflected in the CGEL analysis also by constituency structure, but *have completed* is recognized as a constituent in the BLT approach. This reflects the semantic-informed constituent standard in BLT: as can be found in the CGEL part of Fig. 3, in the clause structure we have a VP *have completed the task*, but it is neither a clause nor an NP, so it is not a constituent in BLT, but once the NP *the task* is stripped away, the purely verbal skeleton *have completed* – which is a span and colored as blue – is of semantic significance: it describes the event going on, and the internal gap for the object as well as the external complement (i.e. subject) gap are interpreted as valency (here the dependency-based nature of BLT is also reflected). So *have completed*, a span in CGEL, gets recognized a constituent in BLT and it fills the predicate slot. This is illustrated in Fig. 3.

There are adjustable parameters in both the CGEL approach and the BLT approach. The aforementioned “what is the head” question and “whether discontinuous constituents are recognized as constituents” are obviously parameters. For BLT, since auxiliary verbs aren’t considered as heads in clauses containing them, the question what are lexical verbs arises, since in many languages, there are catenative verbs that seem to already undergone some degree of grammaticalization, but aren’t typically auxiliary verbs nonetheless. This question decides what is the head in the BLT analysis. Similarly, certain adverbs are actually lexical markers of TAME categories, and hence whether they should be considered as a part of the BLT predicate like auxiliary verbs is a question without a universal answer. The CGEL approach is unable to analyze VSO languages with the subject-predicate division without movements, but similarly, the BLT approach suffers the problem of discontinuous predicate in cases like V2 languages.

The fine structure in a nucleus which is a verb-complement construction can therefore be summarized as follows:

Box 3.2: The fine structure of the nucleus and the term *predicate*

There are fine structures within the nucleus, but they are caught with radically different approaches in BLT and CGEL. The comparison between the two is given in Fig. 3. In CGEL, if *subject* can be defined for a nucleus clause, the nucleus clause is divided into the subject and the *predicate*, and the predicate can be then be further divided by successively stripping off the most external dependent. In a predicator-complement construction, after all adjuncts and complements are separated, the remaining of the predicate is the *predicator*, the head of the predicate, the nucleus clause, and the whole

clause, which is prototypically filled by a verb. The phrasal category of the predicate is typically called the *verb phrase*. It is also possible to have a serial verb construction, where there is more than one predicator-like syntactic item. The CGEL constituent analysis is the immediate constituent analysis plus dependent types annotated by argumentation mentioned in Box 3.1. The constituency tree is the coarse-grained result of the constituency relations in the corresponding generative syntax, which plays a role in deciding binding government and binding between arguments, which verb to move in subject-auxiliary inversion, etc.

In flat-tree approach grammars, i.e. BLT, the only uncontroversial constituent types are NPs and clauses, and all constituents within a larger constituent are placed on the same plane. What aren't arguments in a nucleus clause are all placed into the *predicate*, which corresponds to a span in the verb phrase in CGEL. The predicate in BLT is also said to be a *verb phrase*, or *verb complex* to avoid confusion with the CGEL meaning of the term. What is conveyed by constituency relations in the CGEL approach is alternatively articulated by dependency relations.

Certain constituents acceptable as complements in CGEL, like the direction complement in Chinese, tend to be placed in the predicate position in BLT (see Box 3.1), because these non-argument complements are somehow comparable with auxiliary verbs.

It can be seen that for surface-oriented sketching of previously unknown languages, the BLT approach is more flexible, since there is no need to do surface-oriented binary-branching in-depth constituent analysis, there is no subject-predicate division which is dubious in ergative languages, and surface constituent order is not taken to be directly reflecting the dependency structure. However, since the predicate is the surface correspondence of the verbal skeleton span, it can be expected that the predicate may be more frequently realized discontinuously compared with arguments which themselves are also constituents in generative syntax, and some may want to reduce the content of the predicate to ensure continuousness, while others may not. When there are auxiliary verbs, the CGEL approach naturally recognizes the most external auxiliary verb as the head of the whole clause, the then the second most external auxiliary verb is deemed the head of the VP dependent of the top auxiliary verb, etc., while in BLT, the general tendency is to deem the head of the predicate as the main verb, and not the most external auxiliary verb. Both CGEL and BLT have the problem of noncontinuous constituents, and whether to split them is an adjustable parameter. These parameters are left to the grammarian to decide.

3.4 So-called serial verb constructions

There is no well-recognized definition of serial verb constructions. Under this name several heterogeneous constructions are put together, some of which are similar to verb compounding, while others may be like complement clause constructions but the complement clause is a *vP*.

Similar to Fig. 4, the generative constituency relation-based illustration of serial verb construction in e.g. Chen (2016) can be replaced by the dependency relation-based syntactic process to insert several verbs into a single predicate and alternate the dependency relation between the verbs and the arguments in BLT. Fig. 5 is an illustration of the correspondence between the analysis in Chen (2016) and a BLT analysis. The phenomenon discussed in the diagram is the direction complement construction or direction compounding construction (see § ?? in my notes about Chinese syntax), in which a word indicating spacial movement (picked from a closed category) – which is the direction complement or direction compound – is merged together with a TransP, and the object – in this case *tāng* ‘soup’ – in the TransP also becomes a complement of the direction complement, and by head movement, the direction complement is attached to the main verb – *sòng* ‘send’ here – and hence a compounding verb *sòng lái* is formed, which precedes the object. Now we try to translate the above derivational process to a BLT account:

- The fact that *tāng* is both the complement of the main verb *sòng* and the direction complement *lái* (by appearing in two specifier positions) is reflected by the two dependency relations on the right side.

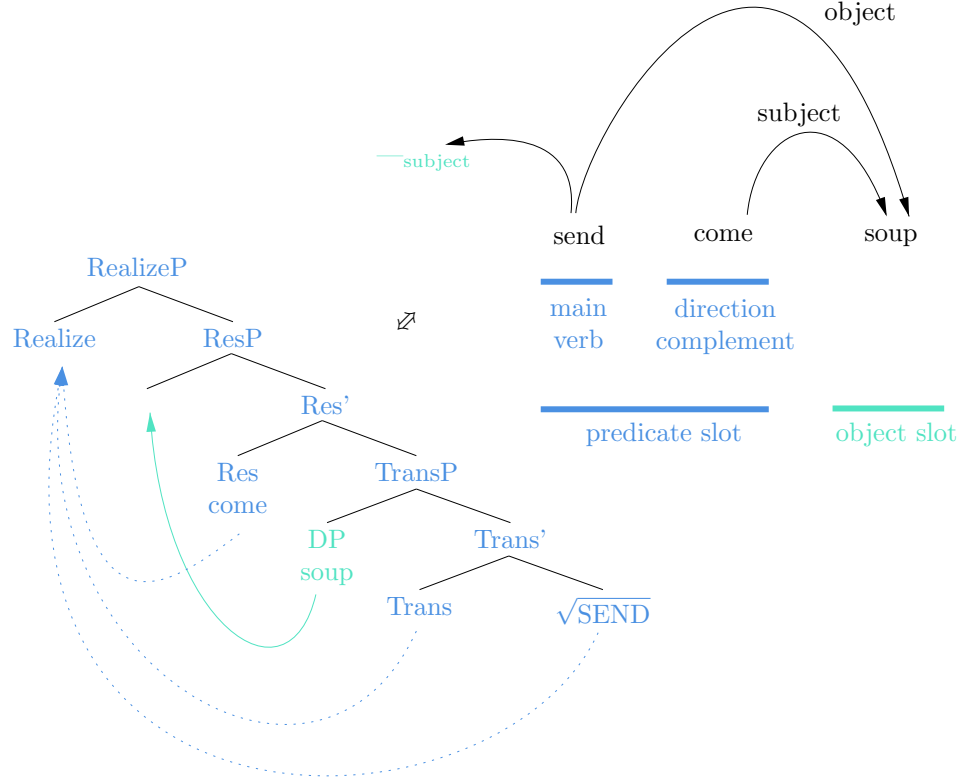

Figure 5: An example of serial verb construction: *send come soup* is the literal translation of the Chinese 送来汤 *sòng lái tāng*, which means ‘send soup here (= send soup and make it come here)’. Based on (74) in [Chen \(2016\)](#), which adjustment to make it compatible with Distributed Morphology.

- The fact that *sòng lái* is the span spellout of the verbal projections minus the object is reflected by putting the two words into the predicate slot. The constituent order information is reflected in a flat-tree way.

Here I intentionally skip the CGEL approach because the complexity of serial verb construction is already comparable with the functional projection that gives rise to the *have been being done* hierarchy ([Ramchand and Svenonius, 2014](#)), and the surface-oriented CGEL analysis will not be substantially different from the BLT analysis shown in Fig. 5.

Here is a problem with Fig. 5: and the verbs appearing in a serial verb construction may be regarded as morphological components of a complex predicator.

4 Morphology

4.1 The notion of *word* and the coverage of morphology

4.1.1 Words as black boxes in syntax

Morphology, roughly speaking, is the study of the inner structure of words. But what are words, anyway? It should first be noted that the definition of **phonological words** doesn't necessarily agree with the definition of **grammatical words**.⁷ BLT spends a whole chapter (chap. 10) to discuss criteria to decide the two. And what is a grammatical word is also not without controversy. Morphosyntactic phenomena used to decide whether a syntactic unit is or is not a grammatical word can be summarized as certain versions of the Lexicalist Integrity Hypothesis, i.e. when it comes to the syntax, the speaker doesn't really feel the inner makeup of the unit.⁸ Today, we know the hypothesis is not really necessary. Extraction constraints exist on all levels of morphosyntax, which can be explained without mentioning *word*. The distinction between word and phrase is likely to be a secondary concept, derived from more fundamental laws of morphosyntax (Bruening, 2018). And the hypothesis is also not one hundred percent correct. What is uncontroversially syntax, like coordination, can definitely see how a word is formed, as in *pre- and post-revolutionary France*.

One way to redeem this definition is to loosen it. We may define the word as a constituent that is somehow small enough. A single noun or verb without any inner structure (like *apple* or *hit*) is a word, and if a construction is unable to take complements larger than a word, then the construction is a word. And if we are sure a construction only take word complements, then whatever complement it takes is a word. The rules can be used recursively to decide the range of words. It is possible to arrive at a self-consistent definition of *word* now. But this is still not without problems.

One problem is the tests shown above are unable to decide whether a function morpheme is a word: the tests to decide whether *American history teacher* is a word work on lexemes (whether the position before *teacher* is filled by an NP or just a nominal word, etc.) and not on function morphemes, especially the most prototypical ones (§ 5.1.2): A slot filled by things like *the* doesn't contain more complex structures, and therefore it's impossible to use substitution tests. One way to fix the bug is to claim that phrases are made up solely by words, so if a function item always appears as an immediate constituent of phrases, then it is a word. Thus, Chinese direction words are nominal words, not suffixes, since they may head NPs. This, however, is problematic for the Latin *-que*: it always appears as a marker of coordination, but it always appears after the initial word of an NP or the head of the NP, while on the other hand usually doesn't participate phonological processes in Latin that targets words. So is it an immediate constituent of the relevant nouns or adjectives, or is it an immediate constituent of the NP? Deciding wordhood according to surface-oriented analysis will hit the wall at a particular time, because surface-oriented constituency relations don't contain all the information. But if we then work with frameworks that are more flexible with the relation between the phonetic form and the underlying structure, like Distributed Morphology, then the notion of words loses utility: if, for example, we recognize *-que* as a grammatical word, i.e. a constituent of the NP and not the nouns or adjectives, then immediately we have to question the status of the perfect auxiliary *have* in English, as one may argue its full form is *have -en*, with *-en* being attached to the verb following it in the deep structure, and ultimately, since the Latin case endings – which anyone with sanity will recognize as affixes – is subject to agreement rules in NPs, one may argue that the case is marked on NPs and then spreads into all nominals within. And since the selectional relation between *have* and *-ing* particles can be described by positing an underlying form of *have -en*, then why not doing the same for subcategorization? Once transformational post-processing

⁷Here the term *grammatical word* isn't limited to function words.

⁸A stronger claim is the speaker doesn't feel the inner makeup of words at all. It is true that native speakers' intuitive partition of words is often problematic when examined closer. The representation of Japanese verbal conjugation in the Kana system – in which stem alternation is invoked – is accepted by most native speakers, but a closer look reveals that concatenative morphology is enough to account for the observed conjugation paradigm, though the stem may end up with a consonant and thus native Japanese speakers do not find the concatenative analysis. But ignorance of minimal analyzable units happens equally in syntax: native speakers often forget to mention important function words when they are invited to introduce a construction of their language. When a native Chinese speaker is invited to talk about the disposal construction, the optional function word *gei* in clauses like *tā bǎ wǒ gei chūmài le* is often left untouched.

rules are allowed, we end up in a theory about features and not concrete words.

A rule of thumb is the more a unit is functional, the more meaningless wordhood is in pure morphosyntax. (Wordhood of function items is still definable using standards in § 4.1.2 and § 4.1.4, but this is not so useful for people only curious about the structure of the grammar.)

Another problem is the resulting definition is often too broad and hence goes against with native speakers' "common sense". For example, *American history teacher* may be argued to be a word. Its inner components are hard to be extracted out in syntax. Attributives never go into the constituent. The form **late American history teacher* is not grammatical, and hence in the construction which starts with the field of learning and ends with *teacher*, the field of learning part must be a word, so *American history* is a word, and *American history teacher* is also likely to be a word. But this of course conflicts with the orthographical standard of wordhood. In some languages like Chinese, wordhood defined by the above morphosyntactic tests differs so much from everyday intuitions, making people wondering whether it is a good idea to just throw the term *word* into the trash bin.

4.1.2 Words as minimal utterance

Another way to distinguish words is not based on morphosyntactic tests done by linguists, but the native speakers' intuition in discourses: a word may be defined a smallest unit that appears in metalinguistic discourses, or maybe it is defined as a smallest unit of ordinary utterance. Here the definition of *word* relies more on the condition of being somehow minimal, rather than on being a unit that is felt by the speaker in actual discourses, because many – actually most – morphosyntactic constituencies that are clearly there (which can be tested using standard constituency tests) are never cited in metalinguistic discourse, and they are of all sizes. What are universally realized by the speaker in intuitive language use seem to be limited to NPs and clauses in syntax, the two being the only constituency types recognized in BLT or in other words, two maximal functional domains in generative syntax, namely the DP domain and the CP domain (see § 1). In this perspective, the relation between morphemes and words is similar to the relation between clausal dependents and heads and clauses. Consider the theory on categorizers in Distributed Morphology, for example. A categorizer phrase, presumably a phase, adds category labels to the stem, without definite categories, which resides in the lowest position of the whole functional projection, in the same way CP and TP grammatical relations are added to a *v*P. What singles words out is they are the *smallest* units that can be cited.

This view, unfortunately, also suffers from several issues. The most important problem is speakers sometimes do cite affixes. Consider the following dialogue:

- (11) – You mean 'pre-revolutionary', or 'post-revolutionary'?
– 'Pre-'.

The second problem is "appearing independently in discourse" is not self-consistent once several standards are considered together. In English, single-verb utterances are rare, but verbs can be cited metalinguistically. So the two standards – minimal everyday utterance and minimal metalinguistic utterance – run against each other. The third problem is the status of function words as words is challenged in this view: the article *the*, for example, never appears on its own as an utterance, but since it appears as a dependent in the NP, it has to be a word, not a morpheme. Dixon seems to be content with this, since in BLT § 1.11 he says there is no need to treat "function words" in the same way as lexical ones: the former are grammatical markers that can be enumerated in the grammar and it is even appreciated if they aren't listed in dictionary.

4.1.3 Words as units with conventionalized meanings

The inner structure of words are subject to fossilization. This gives rise to the so-called criterion of wordhood that a word has a single conventionalized meaning, which can't be seen by looking at morphemes inside it. Thus, the structure of syntactic units directly implies its meaning, while the structure of words, though analyzable, is of primarily historical and etymological interest.

But fossilization exists, of course, in syntax, examples including idiomatic verb-preposition constructions and verb-particle constructions, and periphrastic conjugations as well. The distinction between fossilization of word structure and fossilization of syntax is better regarded as quantitative, rather than qualitative. Fossilization means storing a whole structure in the

lexicon, which of course works better for smaller constructions i.e. so-called morphological trees, rather than large syntactic ones.

As is often said, morphological rules are usually less productive than syntactic ones, and among morphological rules, derivation is less productive than inflection in general. The reason of the first observation is already said above: smaller structures are easier to routinize and hence relevant rules are easier to be eroded. This also explains why derivation is usually less productive than inflection: functional projections involved in inflection are somehow more external, and thus the root together with derivational heads and specifiers constitute a smaller constituent than the root together with derivation heads and inflectional heads, so the former is easier to fossilize. This doesn't mean there is no fossilization in inflection. Fossilization in inflection is the same as collapsing of the functional hierarchy involved, which increases the fusion index of the language. So fossilization of inflection makes the inflection rules more obscure – but there are inflectional rules, after all, because the spellout of the inflectional functional projection span still needs to be concatenated to the stem. On the other hand, fossilized derivation results in new synchronic morphemes (though with historically analyzable inner structures), and the corresponding rules are just gone.

4.1.4 Phonological words

4.1.5 What morphology is about

Several conclusions can be drawn from the above discussion. First, what does the heavy lifting in any definition of wordhood is always minimality: most of the criteria raised apply to what is uncontroversially recognized as syntax as well, and it is minimality that tells words from phrases. Second, different criteria usually give conflicting definition of wordhood. The true meaning of the term *word* will definitely contain some idiosyncrasies of the language in question as well as the personal preference of the author of the grammar (or the cultural tradition, especially the orthography). The term *word* can still be useful as a language-specific descriptive concept, but the grammar writer has to be explicit about what he or she means by the term.

Considering the chaos in defining *word*, expectedly, what is involved in morphology is highly heterogeneous, much more heterogeneous than the case in syntax. The following mechanisms involved are the same as ones in syntax:

- Constituency tree within the word: functional projections (and thus function labels or grammatical relations in surface-oriented terms) that may appear in categorizer phrases. For example, we accept *faithful* as a word, then the function label of *-ful* never appears outside the adjectival categorizer phrase: in English phrases it is never possible to simply add a word and term a noun into an adjective meaning “full of ...”. Function labels within the word may also be the same with the labels in syntax. In Chinese, the predicator-object relation is both found in the clause structure and in verb morphology.
- Span spellout without much nontrivial post-syntactic operations: a span of functional projections are spelt out into morphemes in a transparent manner. Japanese conjugation is a good example of this: the conjugation endings may be seen as auxiliary verbs, which is reflected in the terminology in the School Grammar tradition. This is also seen in syntax: the BLT definition of *predicate* (Fig. 4) is a typical example of how a span is analyzed as a constituent in a surface-oriented theory.

As is said above, the syntactic (in the sense of Distributed Morphology) part of morphology (in the sense of surface-oriented analysis) has nothing different with the syntax (in the sense of surface-oriented analysis) in basic structure building mechanisms. But beside these, languages also have highly localized processes. The following mechanisms are highly localized and therefore are usually only observed in what we call morphology:

- Nontrivial spellout: post-syntactic operations like fusion,⁹ and spellout based on under-specification. Portmanteau is a good example.

⁹Sometimes they are called morphological operations, though the latter term is kind of misleading, since post-syntactic operations work on features and not morphemes. The term *morphological operation* suggests a surface-oriented analysis, which is dual to Distributed Morphology but is not identical to it superficially.

- Phonological realization may combine two grammatical words into one or split a grammatical word into several phonological words. It is even possible for a morpheme of a grammatical word to be attracted by and attached to another grammatical word in phonological realization (BLT § 10.6). These subtleties are usually not introduced in detail in the name of “phonology” and should be accounted for in chapters about morphology.

Of course, nontrivial spellout and phonological rules also appear in syntax (in the surface-oriented meaning): English auxiliary hierarchy, like *have been being done*, involves nontrivial span spellout, while the auxiliary inversion involves head movement, which may be analyzed as an example of post-syntactic operation. Prosody drives lots of syntactic phenomena in many languages, and may even break a word into its parts.

All processes mentioned above are subject to fossilization. Fossilization is another source of so-called Lexical Integrity phenomena (one source being phasehood of categorizer phrases): once a word with complex internal structure is fossilized, its internal structure is of no synchronic significance, and thus “morphological rules” – to be exact, fossilized diachronic morphological rules – are irrelevant to “syntactic rules”.

4.2 Three models of morphology

4.2.1 The Item-and-Arrangement model

For people not interested in recent developments of morphological theories, the Item-and-Arrangement model may be the default model. It is the standard model used in American Structuralism and dates back to the work of Pāṇini. It breaks a word into a sequence (with fixed order by default) of morphemes, each morpheme carries a piece of semantic information.

The major problems of the Item-and-Arrangement morphology, despite its clearness and conciseness, include that in this model the difference between functional and lexical morphemes aren’t recognized, that certain morphological devices, like duplication or deletion, are impossible to account for using purely concatenative morphology, and that sometimes morphemes have no direct meanings.

Distributed Morphology can be regarded as the modern incarnation of the approach, which solves the aforementioned problems. Nonconcatenative morphology is accounted for by “abstract morphemes” which serve as tags for following phonological readjustments. An internal change of vowels, for example, may be modeled as a *simulfix*, which guides the morphology-phonology interface to change the relevant vowels. As [Anderson \(2017\)](#) points out, Distributed Morphology is essentially a theory of features, where alleged “morphemes” undergo so many operations that their correlation with actual morphemes observed in structuralist analysis of languages is undermined.

A more straightforward surface-oriented equivalence of Distributed Morphology is the Item-and-Process approach. Recall that in Distributed Morphology, a functional projection hierarchy is mostly a root surrounded by a series functional heads (which allow span spellout) and their specifiers, and there are phonological rules following the vocabulary insertion to produce things like Semitic template morphology [Tucker \(2011\)](#) or stem alternation. The surface-oriented counterpart of the process above therefore starts from a stem, features it carries and its “arguments” (which, in the generative theory, are the specifiers of functional heads), and then the stem is modified according to the features, and the “arguments” are glued to the modified stem at certain stages, the result undergoing modification as well.

4.2.2 The Item-and-Process model

The Item-and-Process morphology is a variant of the Item-and-Arrangement approach. As is said at the end of § 4.2.1, it works on *lexemes* instead of morphemes, which means functional morphemes are kicked out of the lexicon. What exist are lexemes or “stems”¹⁰ and a set of morphological processes that can be used to alter the lexemes, like adding an ending or changing the internal vowels. The input to the rules are lexemes and features like person or number that the speaker wants the result to carry. This solves the first and the second problems of the Item-and-Arrangement model, and the third problem about meaningless morphemes is also

¹⁰Here is a subtlety concerning the definition of the terms *stem*, *root*, and *lexeme*. See § 4.3.2.

eliminated because the rules are free to add morphemes that bear no specific meanings to meet, say, phonological constraints.

The Item-and-Process model is not without problems. It doesn't explain why most of the time, the Item-and-Arrangement model does a good job. In other words, it seems the Item-and-Process model often overproduces. Maybe it is a good idea to add some of the affixes to the lexicon. Nor does the Item-and-Process model explain why sometimes affixes – i.e. functional morphemes – seem to be somehow “real”, in marginal cases like (11).

4.2.3 The Word-and-Paradigm model

The Word-and-Paradigm model is the modern revival of the framework of traditional Latin (and Greek) grammar. It regards words – and sometimes periphrastic inflection forms like *have been working*, so to be precise, a better term for the Word-and-Paradigm model is Item-and-Pattern – as the smallest units in grammar, carrying the information of the stem and (morphosyntactic, not inherent) features like case and number, and all of the information is packaged into *one* form, without real compositional inner structures. Words differ only in features they carry form a concrete paradigm, and generalizations can be made to extract abstract paradigms (like Latin conjugations) or schemas or analogical rules from concrete ones. The morphology of a language is represented by a set of prototypical words and analogical rules generalized from them. When a new word is acquired, it is inclined tentatively according to the analogical rules (or in other words, schemas). In the Item-and-Arrangement and the Item-and-Process models, the paradigm is epiphenomenal, while in the Word-and-Paradigm approach, it is in the central stage.

The basic idea of Item-and-Pattern morphology resembles the overall picture of construction grammar, though the former has nothing to do with the innateness debate, because the possible ways people make generalization about word paradigms may be – and are likely to be – limited by domain-specific factors. (People never encode grammatical categories into things like the Morse code, for example.) And we can always replace schema with transformation rules. What really makes the Word-and-Paradigm approach special is psychological reality. If we are just talking about producing all and only grammatical utterances, then the Item-and-Process model (and the Item-and-Arrangement model plus abstract morphemes) is equivalent to the Word-and-Paradigm model.¹¹ But there are some evidences suggesting paradigms are psychologically real. Back-formation can't be easily explained, for example, without assuming speakers do not have paradigms in their brains.

Still, the Item-and-Pattern model is not universally recognized, since it is unable to describe a large part of derivational morphology, like compounding, and we know there is no clear boundary between inflection and derivation (§ 4.3.1) and between functional items and lexemes (§ 5.1.2). And the old problem faced by the Item-and-Process model – which the morpheme-based theory works well in many cases – is not answered, either.

4.2.4 What to do

The Item-and-Arrangement model catches the overall picture of morphology in many languages but is unable to account for nonconcatenative morphology easily. The Word-and-Paradigm or Item-and-Pattern model is strikingly powerful to describe nonconcatenative morphology and implies the psychological reality of paradigms but is unable to catch the psychological reality of morphemes or explain why morpheme-based analysis works quite frequently. The Item-and-Process model is somehow in the middle, which (under some adjustment) emphasizes on the significance of morphemes and has the same productivity with the Item-and-Pattern morphology, but can't explain things like back-formation that implies the existence of paradigms.

What is actually used in grammar writing is a mixture of the three models. Dixon argues strongly for the Item-and-Process model in BLT § 3.13. But it is quite often that terms like *simulfix* (“affix of vowel change”), which implies abstract morphemes that guide nonconcatenative processes, are widely used in grammar writing. The Word-and-Paradigm approach is largely ignored in descriptive linguistics (BLT doesn't mention it), though it is said that in a small corpus situation, the Word-and-Paradigm approach is more efficient for at least knowing something about a language (Copot et al., 2022). This is possibly because of the classical structuralist idea

¹¹There may be mismatches about specific models, like for fusional languages, Word-and-Paradigm models work well, while a Item-and-Process model in which a process corresponds to only one grammatical category breaks down.

that psychological reality doesn't really matter in a descriptive grammar. The term *paradigm*, though, frequently appears in grammars.

4.3 Types of morphology

4.3.1 Inflection v.s. derivation

It's sometimes useful to distinguish between derivation and inflection. Distinction between derivation and inflection is useful in some languages, but not others. In the former case, we can define stem easily: it's something that may or may not undergo some derivation, but not inflection, and after proper inflection it becomes a full word. For some other languages the distinction between derivation and inflection doesn't make sense.

Some people claim that inflection is always subject to agreement and derivation is not. This is not the case in Dyrirbal. In Dyrirbal, the comitative case can stack with another case marking the argument role, so it may be seen as derivation suffix. However, it shows agreement between the adjective and the head noun.

Zero inflection marker is a convenient term when other configurations of the same category are marked.

4.3.2 Historical v.s. synchronic morphology

As is said in § 4.1.3, erosion of inflection usually means fusion of several inflectional endings, and the paradigm is still there after all, while erosion of derivation means creation of new synchronic morphemes. For languages with historically rich morphology that has been largely simplified, like English and even Latin, the linguist may notice that most of the derivation devices observed in the lexicon are no longer productive. Historical morphology is no longer relevant for today's native speakers: if one item is derived from another using a historical morphological device, then in purely synchronic considerations, no regular relation can be established between the two: we know *in-* is a negative prefix, but *indifferent* doesn't identically mean 'not different': there is a shift in its meaning. In this case, the relevant affixes are not even a part of the grammar, and hence not a part of the synchronic language (they are never supposed to be a part of the lexicon, strictly speaking, and now they are also not a part of the grammar): they are a part of the history. It's also possible that a mechanism is still in use today, but there are already some shifting in the meaning (or even form) of a particular result of that mechanism. This is just the counterpart of idioms in syntax.

In syntax there are also counterparts of totally eroded mechanisms: *till death us do part* is an archaic form, invoking the SOV constituent order, but since it's in the Book of Common Prayer, the phrase is still in use today as a whole. Having rich recognizable but no longer synchronically analyzable processes is a feature of morphology as compared with syntax, but it's more a quantitative problem: again, a clear border between morphology and syntax can't be drawn.

The fact that derivation creates new synchronic morphemes – synchronic roots, to be exact – with analyzable historical inner structures is invoked by some as a definition of the term *derivation*: whatever creates new lexemes is derivation. But here comes the question about what is a *new* lexeme. Does valency changing devices create new verbs? And if English were a language in which adding *-ly* to an adjective strictly created adverbs with meaning of 'in the manner of ...', then would this process create new lexemes? The claim that derivation creates new lexemes has nothing essentially different from "derivation corresponds to inner functional projections", and the latter inevitably involves endless disputations like whether the passive is derivational. If we understand "creating new lexemes" as "creating new synchronic roots (though still with analyzable inner structures)", then the claim that derivation creates new lexemes has no essential differences with "derivation is kind of historical". Under this definition – that derivation is historical while inflection is not – the tendency that derivation happens before inflection becomes truism.

4.4 Morphological devices

See BLT § 3.13, § 3.14, § 5.2, § 5.3, § 5.4. Here we introduce different morphological operations and how they are labeled in the Lepzig Glossing Rules. The terminology adopted here is slightly

different from Dixon's, as the latter insists only morphological units in concatenative morphology can be said as morphemes.

4.4.1 Concatenative morphology: affixation and compounding

In concatenative morphology, we can distinguish “free” and “bound” morphemes. This doesn't work for nonconcatenative morphology for obvious reasons. There are people defining free morphemes as morphemes that are independently utterances, but under this criterion, most function words (type 3 and type 4 in § 5.1.2) are bounded, and certain morphemes that are of course not themselves words may appear as single utterances in certain occasions (as in (11)). Concatenative morphology includes **affixation** and **compounding**. An **interfix** is something that must appear to link other morphemes but doesn't have any semantic meaning. Concatenative morphology is almost universal, with exceptions of perhaps several totally isolating languages. Affixes (as well as compounding) are labeled as prefix-compound-compound-suffix.

A **clitic** is grammatical item with certain degree of grammatical wordhood yet doesn't have independent phonological wordhood. It's possible (and not rare) that certain in-word phonological rules like assimilation doesn't apply on a clitic, like the case of Latin *-que*, but *-que* still has to be appended to the head of an NP as well as the first word. Clitics are labeled in the format of attached.word=clitic.

The fact that grammatical wordhood and phonological wordhood allow certain degree of discrepancy means whether something is an affix or a clitic or a grammatical word should be decided according to a usually highly nontrivial procedure. First, if a morphosyntactic item surely belongs to grammatical word structures only and not phrasal structures, then it's an affix, and otherwise it's a grammatical word. A grammatical word is then classified according to phonological wordhood, not syntax (and note that for function words, sometimes discussing whether something is a word is meaning less (§ 4.1.1)).¹²

And now here is the problem of the influence of the definition of wordhood on distinguishing affixes from grammatical words. We have seen that tests used to distinguish grammatical words are not without controversies, and it's possible that under a particular definition of grammatical words, there are morphosyntactic units that clearly only appear in grammatical words, but they happen to have independent phonological wordhood. Actually, the suffix *-like* may just be an example: it's not quite rare to see things like *Distributed Morphology-like* (for example in the wording of Baker and Vinokurova (2010)), and despite the grammatical wordhood of the whole expression (it can't be added after an arbitrary NP, etc.), there seems to be a pause between *Morphology* and *-like*, and hence the latter may be regarded as a phonological word, though grammatically it's a suffix. There seems to be no good terminology to tell it from affixes like *-ize*. Still, it's important to realize things similar to the word-clitic distinction happen inside words, and phonological observation doesn't necessarily reveal the grammatical relations.

An example similar to the above example but involves a phonologically dependent affix is the word *Feynman diagrammatic*: from the morphosyntactic perspective, it definitely is [*Feynman diagram*]-*tic*, instead of *Feynman* [*diagramma-tic*], but the latter is the accepted analysis in printing.¹³ which roughly means the latter is the accepted phonological analysis. So there is a mismatch between phonological and morphosyntactic standards of wordhood (§ 4.1.5). If *Feynman diagram* were analyzed as a phrase, then *-tic* would be analyzed as a clitic.

A grammatical system (like tense) may be realized as affix, clitic or separate grammatical word. Here is a generalization that is not merely definition: the latter two are unlikely to be associated with every word of a phrase, but an affix may be (for example, Latin case). A case marker at the end of an NP is often a clitic. Note, however, that there are no necessary restrictions. It's possible that a dialect of a language place the case marker to the end of the NP, while another dialect place the case marker after the head of the NP. The phonological-morphological process involved is the same between the two dialects, but if we claim that a case marker after an NP *must* be a clitic, then we have to make the strange claim that the *same* morphological process results in a clitic in one dialect and an affix in another. The problem here is exactly the problem in § 4.1.1: morphosyntactic tests are unable to completely settle down what absolutely is an affix and what absolutely is a grammatical word, especially when

¹²This also means a clitic doesn't necessarily “wander among words in the phrase”: this is the case for latin *que*, but the English article *the*, in daily speech, is just a clitic and it definitely doesn't go around in the NP.

¹³By the way, this is also a demonstration that *Feynman diagram* is a grammatical word, because it's subject to grammatical processes that only words are able to undergo.

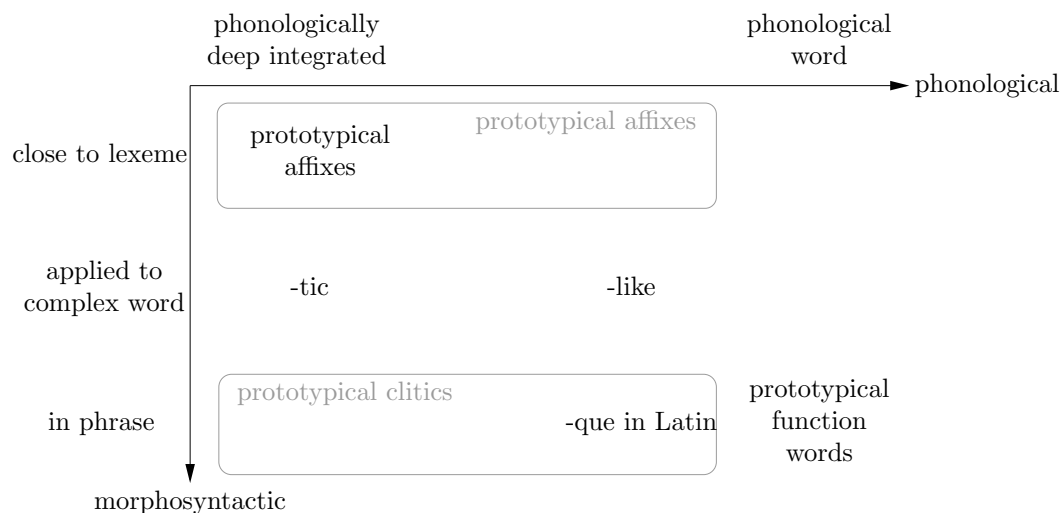

Figure 6: Classification of function items

the functional item in question has narrow distribution. So deciding whether something is an affix or a clitic sometimes is impossible.

Here is a list of frequent functions of compounding:

- Noun compounding as a mean of derivation
- Verb compounding,
- Noun incorporation

4.4.2 Non-concatenative morphology with easy-to-recognize morphemes: infix, circumfix, transfix

An **infix** is annotated as `morpheme[infix]morpheme`, which is inserted into an otherwise complete morpheme. A **circumfix** is annotated as `cirfumfix.meaning1-morpheme-circumfix.meaning1`.

4.4.3 Internal change: suprafix, simulfix

A **suprafix** is a suprasegmental change, including tone, prosody, stress, or nasalization. a **simulfix** changes one sound in an existing morpheme, like *foot* → *feet*. Simufixes are mostly vowel changes, but consonant changes are also attested. A **transfix** is an abstract morpheme used to describe template morphology as seen in Semitic languages, where the root is a template and the affix is a discontinuous one inserted into the root. In this wiki, it is glossed as morpheme. A transfix can be seen as a generalized simulfix. Reduplication is modeled by abstract morphemes named **duplifix**, annotated as `lexeme.the.function.of.duplication`.

Things repeated may be initial syllable, first two syllables, last syllable, and the whole word; each of them may have a distinct function. For nouns: plural, diminutive, selection ('long' -*ī* 'things that are long') For verbs: repeating, intensive, continuous. But generally this operation can mean anything. When annotated, reduplication is treated similar to affixation, but with a tilde: *yerak-rak* in Hebrew means "greenish" and is tagged as `green~ATT`.

Subtraction is modeled by **disfix**. For example in Somoan we have *silaf* → *sila*.

5 The lexicon

5.1 Overview

5.1.1 What is in the lexicon

For grammars, the lexicon is the end of top-down partition and the start of bottom-up description. Contents in this section are mainly about what are likely to appear in the lexicon, and how argumentation can be made to assign category labels to them.

Lexicon here means the surface-oriented one, the one that people without much knowledge on the generative tradition can also use. That is, we zip the formative list and the exponent list into the library of lexemes and processes on it, and the Encyclopedia is represented by idiom entries. In our surface-oriented analysis, the three lists in Distributed Morphology are mixed into one single lexicon. This is of some benefits for diachronic research, since now fossilization, collapse of the inner structure of words, etc. are totally within the lexicon, without problems like whether *kick out* is created by $\sqrt{\text{KICK}}$ plus *out* and is interpreted by the Encyclopedia, or is simply $\sqrt{\text{KICK-OUT}}$ plus a word splitting operation. The cost is there is now (morpho)syntax within the lexicon and a lot of lexicon entries (actually most of, since even a word like *get* is a categorizer phrase) are no longer atomic.

Taking a look at § 4.1, some ideas can be grasped about what is to be stored in the lexicon – and where are the relevant controversies.

It is often said that the lexicon includes form-meaning pairs. This is a oversimplified statement for our surface-oriented single lexicon. If we say *developed* contains two morphemes – *develop-* and *-ed* – and therefore is the composition of two meanings (an action and the past tense), then what about *went*? It contains two meanings compared to *developed*, but it of course contains only one morpheme. It is better to understand the lexicon as a traditional dictionary, in which the meaning of fossilized units that are larger override the meaning of smaller units that make up the former, and regular forms are replaced by irregular forms (or in other words, a single form overrides a composite). Under the general entry about *kick* we may see a more specified entry about *kick out*, which overrides the definition of *kick* plus *out*, and in the entry about *go* we will see *went* replace *go-ed*. Still, the idea of form-meaning pair is important when building an actual lexicon, since it is the main source of minimal pairs, especially in the initial stage of investigation.

A morpheme may have several alternative forms or **allomorphs**. Again, for languages in which non-affixation processes are frequent and/or fusion is strong (as is the case in Latin: a noun inflection suffix should be analyzed as one or three morphemes?), we can't use these terms and should work with a more general Item-and-Process approach.

5.1.2 Notes on the lexical-function distinction

In my notes about Zhu's book § 2.1.3, I note the ambiguity of the lexical-function dichotomy. The parameter determining the dichotomy may be

- whether a class (noun, verb, determinatives, etc.)¹⁴ in the lexicon is open, or
- whether a class has a real category label (nouns, verbs, etc. do – and in Distributed Morphology they are called categorizer phrases – while words like *the* do not, and whether prepositions have categorizers are not clear and may have crosslinguistic variations (Deacon, 2014)), or
- whether a class is a part of the grammar.

There are correlations between the three parameters. By definition, if a class is a part of the grammar, then it has to be closed, and crosslinguistic generalization tells us a class without any category label is a part of the grammar and hence is closed. The latter generalization may have exceptions, because the term *class* isn't yet clearly defined, and if you recognize things like ideophones as a uniform class in the lexicon, then it is open to a certain extent and may be argued to be outside the grammar and has no definite category labels: they are categorized according to need. But of course ideophones are grammaticalized, and if they are like typical nouns or verbs when they fill argument slots or predicate slots, the ideophone class is not on the same plane with classes like noun or verb, and can be split into subclasses that belong to nouns, verbs, etc. In this case, the term *ideophone class* is actually not about category labels but about etymology. On the other hand, if the ideophone class truly has largely uniform morphosyntactic appearances (like prototypically appearing in the topic position, etc.), then there are of course a separate category label for the class and thus they are just another ordinary class in the lexicon.

So now concerning the lexical-function distinction, the lexicon can be divided into the following parts:

¹⁴Note that here the term *class* is intentionally used instead of *category*, because I'm going to talk about category labels later, which are not seen in some classes like determinatives, and I also avoided the term *word class* because there are also classes of morphemes.

1. Open, with real category label, not a part of the grammar: these classes are prototypically lexical. Ordinary nouns, verbs and adjectives are just of this kind.
2. Closed, with category label, not a part of the grammar: these classes are so-called “closed lexical” ones, examples of which include Japanese verbal adjectives.

It’s subtle to decide how closed a closed class should be. Japanese verbs still rarely take new members, like *gugu-ru* ‘to google’, and this may lead some to claim there are new real closed lexical classes.

3. Closed, with category label, a part of the grammar: the most typical class of this kind is the pronoun class. Things like verbalizer or nominalizer are also in this type.

There are some subtleties between the last kind and this kind: should things like Chinese direction words be considered as a part of the grammar? How about prepositions? English prepositions are not just syntactic case markers: some, like *at* or *during*, may be so, but others, like *up* or *down*, have meanings still analyzable in verb-particle constructions as well as predicative distributions (*the network is down*). These facts can be accounted for by assuming a uniform preposition class, but allowing prepositions to be transitive or intransitive, and in this perspective, they are of course not simply case markers.

4. Closed, without category label, a part of the grammar: the prototypical function classes. They are about the structure of the language, not concrete contents. Still, there are marginal examples lying on the boundary between the third kind and this kind: Chinese direction words, again, are sometimes said to be postpositions, and this wording makes people to feel whether it’s a good idea to just assume Chinese direction words are category-less grammatical items.

It’s also possible for classes of different lexical degrees to overlap. A verb may have another role as an auxiliary verb, which may be considered as belonging to a type 3 or type 4 word class.

A final remark on the lexical-functional distinction: recall that so-called lexical items are just fossilized Distributed Morphology trees with a core root and a smallish functional hierarchy (possibly containing some “arguments”, realized as compounding lexemes), and functional items are span spellout of a functional hierarchy. This helps us to understand things like closed verb or adjective categories. Items in a category in type 1 basically have one-to-one relations with roots that can be categorized by a certain categorizer. If a language decides to realize all roots first as nouns, we will have a closed (Cinque and Rizzi, 2009) TODO

5.1.3 Lexemes and affixes

As we say in the above discussion as well as § 4.2.4, the building blocks of a language contain lexemes and morphosyntactic processes, the latter including affixes. Affixes can be classified according to § 5.1.2 as well. They are always grammatical so they are always sorted into closed classes. So the parameter left is whether an affix has a real category label. The English *-tion* is a suffix with a noun category label, while *-ize* is with a verb category label. Some affixes are without category labels. On the other hand, *dis-* seems to lack any category: we have *disadvantage*, which is a noun, but *dislike* is a verb.

Since affixes are purely grammatical (or even historical – see § 4.3.2), one may insist them being excluded from the lexicon. But this is faced with the problem mentioned in § ?? in [my notes about Latin](#). The blurred line between lexical and function items means any ambitious dictionary editor doesn’t dare to skip the latter. Also, there are often so many of grammatical items (whoever doubtful about this can take a look at the Latin correlative table) that most grammars simply ignore most of them for brevity. and the burden of documenting them is shifted to the dictionary editor. And for practical reasons, searching for something in a grammar is exhausting, and to keep everything in the dictionary is a good idea.

5.1.4 Lexicon entries

Recall what is covered in a dictionary entry – you will need something like “advanced learners’ dictionary”, because sometimes a dictionary hides important information like subcategorization of a word into examples containing the word. For a lexeme, at least the following things are required:

- Enough information to find all (at least frequent) morphological forms. Note that in dictionaries for well-known languages, it's often the case that the stem is not given. What is given instead is the so-called principal forms, as in standard Latin or Japanese dictionaries.
- Subcategorization: how the word takes complements. The term *subcategorization* is usually seen together with verbs, but of course nouns also have subcategorization: we have *the fact that ...* but never **the fact to ...*. Sometimes the subcategorization pattern can be found by semantic hints. Sometimes it can't: what's the difference between *accuse of* and *charge with*?

It's possible for a lexeme to have several subcategorization patterns. Then there are transformational relations between these patterns. A good grammar should include frequent subcategorization patterns and to recognize function labels in each of them: which one is better named *direct object*, what does *oblique* means, and so on.

It's possible that the subcategorization pattern of a lexeme varies with respect to the environment??

-
- Agreement information:

Sometimes we need more subtle information:

- Transformational properties of constructions headed by the lexeme. For example, we have *I'm given a gift ward*, but not *?he was bought a gift*. This shows the difference between *give* and *buy* in passivization.
-

Everything concerning the properties of constructions headed by verbs – mostly clauses – should be in principle recorded in the lexicon, as long as the properties are not results of general morphosyntactic rules or smaller constructions (for example, it's possible that in a language, a verb taking a preposition phrase complement, and because of the properties of the preposition, the NP following it can't move out of the nucleus clause).

5.2 The noun category

Despite some morphological and syntactic varieties, all languages have nouns. A noun is typically a head of a phrase filling an argument slot (see Box 3.1) – this distribution feature is the *prototype* role of nouns, and also an important criterion to recognize a noun class. This is not the only criterion: for languages with rich morphology, the paradigm of prototypical nouns is a useful tool to probe other nouns.

5.2.1 Possible distribution

5.2.2 Semantic classification

5.3 The verb category

5.3.1 What is recorded in the dictionary entry of a verb

Verbs may just take NP arguments

Here is a list of what needs to be described in the dictionary entry of a verb if the dictionary is expected to provide full information instructing how to build a sentence from words:

- Grammatical categories marked on the verb and

5.3.2 Semantic classification

5.4 Distinguish verbs and nouns

In BLT, how to tell verbs from nouns is discussed in chap. 11. In many languages, nouns can take the prototypical role of verbs, being the predicate in the BLT sense, and/or verbs can take the prototypical role of nouns and head an NP. These languages are claimed to lack the distinction

between nouns and verbs. This is confusion between form and function. Such cases are discussed in § 5.4.1 and

Above are all morphosyntactic criteria. Note that semantics should not be the key point when classifying words. Thorough analysis of semantics should be done *after* establishing word classes.

5.4.1 Verb as NP heads

Sometimes verbs are able to head NPs. Note this is different from complement clauses and free relative clauses: there is usually no place for TAME categories or prototypical clause adjuncts in NPs, and the marking of arguments may also be quite different. The comparison between verb nominalization and non-finite clause is a good demonstration of this point (§ 9). In all languages with clause embedding in argument slots, something headed by a verb appearing as an argument is nothing strange, but if a real NP is headed by a verb without any explicit derivation, this will be an intriguing case.

5.4.2 List of useful tests

Argumentation is required to see whether the prototypical noun class and verb class really have largely overlapping coverage, and if so, what tells verbs and nouns apart. It is often the case that one or more of the following happens, and in this case, only a noun-verb distinction can explain the relevant phenomena:

- Verb and noun may undergo different morphological process: word-class-changing derivations, reduplication, etc.
- Verbs in argument slots show meaning different from their meaning when being the predicate, hinting a zero derivation. Since the derivation is irregular, it may be actually be historical rather than synchronic (§ 4.3.2). This is exactly the case in English. The verb version of *father* means "to be sb's father", while *baby* has no meaning of being sb's baby.
- There are clearly noun-to-verb and verb-to-noun derivation mechanisms (often irregular and are historical), and they show similar semantic behavior of so-called "noun used as verb" or "verb used as noun" mechanisms. If we do not realize the example of *father* in English, the fact that English has a clear noun-verb distinction can also be demonstrated via the following argumentation. In English, we have *witness* v. → *witness* n. 'someone who witness', and once this is compared with *observe* v. → *observer* n. 'someone who observe', it can be seen the noun version of *witness* is from derivation instead of the verb-as-noun mechanism.
- Nouns acting as predicates are almost always intransitive, especially when there are many, many normal transitive verbs. This can be easily explained by assuming the nouns undergo a zero derivation and the derivation affix is intransitive.
- A NP headed by a verb often has more restricted structures (this is also one criterion that defined pronouns). NPs headed by a verb are possible to reject possessive affixes. NPs headed by a verb may obligatorily take an "article" - a nominalizer, actually.
- So-called NPs – verbs in argument slots – may actually be clauses, which can be found by signs like no adjective modifiers are permitted.
- Typical nouns may have a noun class or gender system (which can be reflected by a classifier), number feature, definiteness, and/or case. So-called NPs headed by a verb often lack one or more systems.
- Nominal predicates may be unable to have TAME categories or be modified by certain adverbs or have uncanonical behaviors in serial verb constructions. They may also undergo fewer valence changing devices.

Box 5.1: Distinguishing nouns and verbs

Here is how to distinguish nouns and verbs: first accumulate a set of prototypical nouns and verbs, and then make a sketch of the prototypical NPs and clauses, and then use word distribution in them as testing standards to divide nouns and verbs. It should be remembered that surface-oriented analysis categories is just a projection of the underlying composition of features: “noun features” and “verb features” are universal, but what it means to be a noun is not.

5.5 The adjective category (or categories)

See BLT chap. 12.

The prototypical function of adjectives is to modify an NP. But whether it is really necessary to introduce a single adjective class is often disputed. To describe a single language, any terms may be used, and it is alright to merge adjectival classes into the verb class or the noun class. However, for unified description and role in typology (to “provide feedback into the basic linguistic theory”), we need to recognize a separate adjective class, because what can be said as adjectives have robust cross-linguistic functional properties and semantic content. If we do not set an adjective class, then typical adjectives (those in English) have to be compared with a subclass of a language lacking prototypical adjectives, creating unnecessary obstacles.

Adjectives can’t be distinguished using a single criterion. Latin grammarians use the existence of a gender feature to distinguish adjectives, which fails for the genderless language Finnish. However, in Finnish, some words take possessive suffixes but not comparative and superlative suffixes, but another class of words is the opposite, so we can name them as nouns and adjectives.

When analyzing languages where adjectives are like verbs, linguists often use the term “stative verb”, but if so, in order to be consistent, they have to admit that in Spanish, adjectives are “stative nouns”. Here we see the effort to remind people that something in a language is different from European languages unfortunately makes them to ignore important language universals. Avoiding Eurocentrism unfortunately creates more Eurocentrism.

Adjective is a highly heterogeneous category. Any word class with the following properties can be named as an adjective class:

- It may (but not necessarily) make a statement that something has a certain property, either by a copula clause, or by a clause headed by the adjective, just like an intransitive clause.
- It may (but not necessarily) modify an NP (and sometimes a verb, with explicit derivation or with zero derivation).
- It may be in a comparative construction (which may not exist for certain languages).

According to its behavior in these constructions, we can classify adjectives into

- Type 1: verb-like. It can be head a predicate which may be slightly different from typical verbs in
 - how it is modified when acting as a predicate (less adverbial constituents are available, for example);
 - that it can be an attributive modifier (but usually only possible via a relative clause for adjectives like verbs; if this can be achieved without a relative construction, i.e. like a typical attributive construction, then the adjective is not likely to undergo similar morphological processes with the noun);
 - that it can appear in comparative constructions;
 - that it can form adverbs.
- Type 2: noun-like. Here is a list of noun-like properties that frequently appear on adjectives:
 - that it may be an NP modifier;

- that it may head an NP;
- that it has similar morphological properties like a noun;
- that it may fill the copula complement position.

Noun-like adjectives are often slightly different from typical nouns in

- that fewer modification possibilities exist for it than for nouns
 - that it can appear in comparative constructions
 - that it can form adverbs
- Type 3: sharing properties with both verbs and nouns in that it can both appear in the head of a predicate and inflect like a noun when in an NP, and sometimes also act as a copula complement.
 - Type 4: different from nouns and verbs. It's different from nouns in that it doesn't undergo similar morphological process with the noun, or maybe its behavior in the copula complement position differs with a typical noun (for example a noun may require an article but an adjective doesn't). It's different from verbs in that it can't appear in the head of a predicate.

A language may have two adjective classes, and the adjective class in a language can be closed and highly restricted. The size of the adjective category is often related to the semantics of adjectives. When the number of adjectives is just a dozen or so, there are likely to be adjectives about

- dimension: big, small, long, short;
- age: old, young;
- color: black, white, red;
- value: good, bad.

When there are more members, physical properties (raw, hard, heavy) are likely to be described by adjectives. Larger adjective categories also code human propensity (clever, rude).

5.6 So-called adverbs, prepositions and other particles

6 Verb and arguments

6.1 Introduction

6.1.1 The argument structures

This section is mainly about argument slots of “prototypical” verbs, that is to say, about simplest clauses without, say, complement clause constructions. That's not to say complement clauses can't be analyzed in the framework of verb and arguments, but since the complement clause construction(s) has much more subtleties, they're to be discussed in § 13.2. And that's not to say this section completely excludes complement clauses. In clauses like *that he becomes ill strikes us*, *that he becomes ill* is definitely a complement clause, but its role – both syntactic and semantic – has almost no difference with NPs (except the dummy subject construction like *it strikes us that he becomes ill*).

Listing all argument slots of a verb, we get its **argument structure**. It should be noted that argument positions in the argument structure are not the same as clausal complement or adjunct types. The latter are so-called A-positions, and may be understood as “surface” argument positions (§ 7.1). The argument structure of a verb is useful in cases beside clausal structures: it also largely decides the structure of the NP headed by the nominalized version of the verb. And even when valency changing is not considered, the clausal complement type of an argument is not purely decided by its position in the argument structure: *John's playing the national anthem* and *that John plays the national anthem* have the same head verb (I mean the lexeme, not the inflection ending), but the agent argument is marked differently. From the

generative perspective, this is because the relations between the verb and its arguments are not created locally: arguments are introduced (probably assigned semantic roles) in the lower projections of the *vP* layer, the accusative case (in accusative languages) is assigned when the *vP* layer is almost finished, and the nominative case is assigned in TP. And this means beside largely semantic discussion of argument structures, alignment is needed (§ 3.1.5).

One prediction – though a quite soft one – made by the light verb theory in generative syntax is that argument positions in the argument structure are not on the same plane. In the argument structure of *paint* as in *I paint the box green*, there are three arguments: the agent, the patient, and the copular complement. We may say the patient *the box* and the copular complement *green* are somehow “closer”, and they may be argued to form a “small clause” (Box 11.1), and the agent *I* is somehow “higher”, and reflexive pronouns usually do not appear in this argument slot. Of course, movement within the *vP* is still possible, and sometimes there is no consistent hierarchy of the relative height arguments: argument A may be closer to argument B under one criterion, while closer to another argument C under another. And we have control and ECM constructions, in which the “object” is both an argument in a complement clause and an argument of the main verb. In practice, many descriptive linguists just ignore this and just enumerate possible schemes of argument structures, often in the name of so-called “semantic-based analysis” (§ 1.1.2). The scheme of argument structure as is found in *I paint the box green*, for example, contains an A argument, an O argument, and a copular complement, and instead of making a generalization like [A *become* [O CC]_{small clause}], a descriptive linguist will just name this as the argument structure of state-changing verb. The fact that the A argument is somehow higher in the position may be implicitly accounted for by the generalization that A argument binds other arguments. The fact that O and CC form a small clause may be accounted for by emphasizing on the correspondence between *I paint the box green* and *the box is now green*.

6.1.2 Alignment

There are usually much fewer complement types than semantic roles. The detailed semantic classification of verbs – and their complements – is quite messy. Table 3.1 in BLT lists the semantic classification of the most frequent verbs in English. There are 16 semantic roles mentioned, and if the linguist just lists his/her testing results of the syntactic behavior of each of them, the reader will be driven mad! A well-organized description of the alignment of a language therefore is based on the mapping relation between complement and adjunct roles and coarse-grained semantic roles. A priori no one knows how to coarse-grain semantic roles so that the resulting “macro-roles” make sense both syntactically and semantically. After periods of investigation, several macro-roles have already been identified. The most important three are S, A, and O¹⁵. S is the only argument in the intransitive clause. A and O are the more agentive argument and the more patientive argument in the transitive clause, respectively. Other argument labels include E (whatever that occurs together in addition to a SV or AVO construction – see § 4.5.2 in [my notes about CGEL](#)), G (the goal-like argument in a ditransitive construction with a meaning of “transferring” – see § 4.5.3 in [my notes about CGEL](#)), and T (the theme-like argument).

If somehow S and A are realized by the same complement type – which is commonly named the *subject* – then the language is **nominative-accusative** or simply **accusative**. If, however, S and O are realized by the same complement type, then the language is **ergative-absolutive** or simply **ergative**. As is shown by Fig. 11 in [my notes about CGEL](#), to say two complement types are essentially the one has a vague meaning: the monotransitive object and the T argument in the English V-G-T construction (*sth.* in *give sb. sth.*) are both analyzed by CGEL as instances of the direct object, but they differ in passivization. The same is for identification between S and A or O. A language can be accusative under certain standards while ergative under others. For details, see § 3.1 in [my notes about alignment](#).

6.1.3 Additional notes on macrorole labels

The labels S, O, and A (and similar ones) used here are relevant to the semantic details of argument structure, but they are syntactic concepts anyway, i.e. concepts that captures a set of grammatical features that occur together. Since they are introduced in a derivational stage earlier than the alignment, in a generative perspective, the S, O, A labels are just aliases of relative

¹⁵Many denote it as P, to be consistent with the A argument (agentive/patientive). In this note I use O to be consistent with Dixon.

positions of specifiers of light verbs, with A being the most “external” argument (SpecDoP, for example) when there are two core argument being present and O being the internal one, and S marking the argument when there is only one. These labels are defined before alignment is considered¹⁶ and are about dependency relations in the *v*P layer, which are connected to properties like binding, but not necessarily about grammatical properties concerning higher layers, like topicalization.

There is some drifting in the meaning of these argument labels. Essentially being functional labels just like *subject* and *nucleus*, these labels are syntactic concepts in some contexts, including “passivization means turning the O argument into S and turn the A argument into E” and “the A argument always binds¹⁷ the O argument, which means O can be filled by a reflexive pronoun bound by A, while reflexive pronouns do not occur in the A position”. The notion of S argument is also an inherently syntactic one, because S arguments in so-called unaccusative verbs are closer to O, not A. When the S, A, O, etc. concepts are syntactic, we may say “the agent argument is marked as A”, or “the goal argument is marked as E”, and complement or adjunct labels are just coarse-grained S, A, O, etc. labels (e.g. the *subject* label is the clustering of A and S), because the S, A, O etc. labels denotes complement types with semantic specification.

On the other hand, there are contexts in which the S, A, O, etc. notations are defined on an almost solely semantic footing: the English G argument shows rather split behaviors in the V-G-T and V-T-pG constructions, as is shown in Fig. 11 in [my notes about CGEL](#). Now we do not say “the agent argument is marked as A”, but “the G argument is marked as the indirect object in the V-G-T construction”. Note that in this case there is no simple relation between complement types and the argument labels: for example, in Fig. 12 in [my notes about CGEL](#), The O argument and some instances of the T argument are marked as the monotransitive object, while the rest of the instances of the T argument are marked as the ditransitive direct object, so there is no surjection relation from argument labels to complement types, but nor is there surjection relation from complement types to argument labels.

The requirements of uniform syntactic behaviors, of uniform semantic behaviors and of conciseness when coarse-graining semantic roles often can’t be satisfied together, giving rise to the above phenomenon.

6.1.4 What this section is about

So in principle, a two-step description is required for describing the relation between arguments and the verb: the first step is formation of the argument structure, in which labels like (syntactic, corresponding to rough positions in the *v*P) S, A, and O are assigned to arguments, and the second step is alignment, in which more “concrete” function labels like “subject”, “direct object”, “subject-possessor” are given to S, A, and/or O arguments, which involves constituent order, case, etc. Alignment is a process that eats an argument structure and produces a semi-finished clause, which, after marking of TAME categories and so on, becomes a complete clause.

The problem with this approach is labels like S, A, and O are not visible in surface-oriented analysis: clausal dependent types can be found using argumentation like § 4.5 in [my notes about CGEL](#). Descriptive grammars, therefore, often mix the discussion on frequent argument structures and the discussion on their alignments together, and we will see the familiar notion of “a verb that has a subject and an object”, instead of the more appropriate “a verb that has an A argument and an O argument, which are realized as a subject and an object in an active finite clause”. Still, the macrorole notations S, A, O, etc. are better used when discussing valency changing. And we can see a mixture of typical argument labels and clausal complement labels in descriptive grammars: in [Jacques \(2021, § 8.1\)](#), we find *intransitive subject*, *transitive subject*, *object*, *theme*, and *location* are listed together. Things like argument indexation, though are highly dependent on the TP layer, are also introduced in the chapter about argument structure [Jacques \(2021, chap. 14\)](#).

The output of the morphosyntactic machine described in this section is a semi-finished clause with no adjuncts (or “peripheral arguments” and adverbs), no TAME categories, and no other categories like negation or valency changing. TAME categories are necessary for a clause to stand alone – actually the case marking of external arguments (like the subject in accusative

¹⁶That’s not to say alignment has nothing to do with *v*P: the accusative case is often argued to be assigned when *v*P is finished, for example.

¹⁷The term in BLT chap. 13, Appendix 1 is *control*, but *control* has its specific meaning in a class of verbs that take an object and an infinitive complement clauses.

languages) is done after T enters derivation. Thus, once TAME categories are trivially added, the output of this section is a nucleus clause (§ 3.1.1), which is subject to information packaging operations, relativization, etc. Often, the term **canonical clause** is used to denote the output of this section, which is the most transparent realization of the argument structure.

6.2 The S, A, O typology

Discussion on prototypical transitive and intransitive verbs is usually the first step to understand verb subcategorization and alignment in a language.

6.2.1 The notion of *subject*

(4) is a flat-tree analysis, but there are several evidences suggesting a fine-grained hierarchy is useful even for surface-oriented analysis. For accusative languages, the S and A arguments are and hence are identified as the *subject*, and we have the following facts:

- The subject is much easier to be extracted out of the nucleus, which can be explained by the theory that it is somehow higher and movement operations are localized.
- The quantifiers of the subject and internal complements, explicit or implicit, demonstrate a stable scope hierarchy: the scope of the subject quantifier is always larger. When talking about a charity organization, one may say *every woman helps three boys*. Here, the subject is bounded by \forall and the object is bounded by ‘there exists three ...’, and $\forall > \text{three}$ and $^* \text{three} > \forall$: the meaning of the sentence aforementioned is ‘for each woman, there are three boys that she helps, but I do not know who they are, and possibly the boys Sarah helps aren’t the boys Lily helps’. After a seemingly trivial passivization, we get *three boys are helped by every woman*, which means ‘there are three boys – I don’t know who, but anyway there are three – who are helped by every woman in our organization’, and we have $\text{three} > \forall$ and $^* \forall > \text{three}$. If we assume the semantics is related to the syntactic structure at least partially, then this is a piece of evidence that the subject is higher in the syntactic tree, no matter what its semantic role is.
- If the subject is indefinite, then it is by default bounded by \forall , TODO: really???
Some notes about BLT chap. 13, Appendix 1: TODO: S argument and A argument are by default bounded by \forall , while O is bounded by \exists – is this cross-linguistically correct? This also explains why verb-object incorporation is frequent: *a cat kills some animals* = *a cat kills*. It seems the only argument – be it peripheral or core – that is by default bounded by \forall is S in intransitive clauses and A in transitive clauses (which may be seen as a double check). What’s the counterpart in syntactic ergative languages?
- Verb-argument incorporation, nominalization, etc. (for example compare *solve problem* and *problem solving*) usually happens between the verb and the internal complement(s), not between the verb and the subject.¹⁸
- If there is something looking like reflexive pronouns, then it usually follows the Government and Binding scheme, and using this as a test, the subject is always predicted to occupy a higher position.

The list can go on and on.

The above discussion on argument structure can be summarized as the follows:

Box 6.1: Argument structure and argument labels

Coarse-grained semantic roles based on similar syntactic and semantic properties include S, A, O, G, T, etc., and the alignment of a language decides the relation between these argument labels and complement and adjunct types. The exact meaning of the argument labels varies. Sometimes these argument labels are just clausal complements subclassified according to the semantics, and sometimes they are mostly semantic.

¹⁸Grammaticalization of a span is also in principle possible, so incorporation between the verb and the subject may still rarely occur. But note that operation on span is usually seen for functional hierarchies, in which what are spellout as a single word are highly lightweight functional heads, not more substantial lexical categories.

6.3 The G-T typology

7 Valency changing

7.1 Descriptive framework

Definition of S, A, O, etc. of course doesn't work without modification for passive sentences and other valence changing constructions. Here we need to talk about *surface* and *deep* labels. For example, in passive sentences, it is convenient to talk about the "surface S" which is the underlying O. No one would think of the surface S as agentive in the argument structure in any sense. So here the question is what *surface* and *deep* mean.

7.1.1 Comparison with canonical clauses

The most direct way to define deep S, A, and O may be transformation relations: the deep S, O and A arguments of a clause is the S, O and A arguments in the canonical form of the clause. Thus, in English passivization construction *he was arrested*, the deep A is not specified and the deep O is he. The canonical form of this clause is *someone arrested him*, where *him* (we are not talking about alignment so *he* and *him* are considered as identical) is O, so in the passive clause, the deep argument position of *he* should be O as well. Contrary to the deep definition, the surface S, A and O are defined by the similarity in *alignment* to S, A and O in an active canonical clause. We should remark that though the deep definitions of S, A and O are largely independent to the details of alignment, this is not the case for the surface labels.

Note that we don't specify what grammatical relations are involved in the definition of surface argument slots. What we just say is "what marking strategies that define the surface S, A and O in a canonical construction also define the surface argument labels in a non-canonical construction". What *alignment* means is to be decided by the internal structure of the language in question. In both syntactic and morphological ergativity, we say "S and O are marked similarly", but what makes them similar in alignment need further specification. A single notion of "surface A" contains no information, while a single notion of "deep A" does carry some information (like binding properties). Essentially, the surface argument labels are A-positions (SpecTP, SpecTransP, etc.), and the alignment details used to distinguish them come from peculiarities of the functional projection in clause structure in the language being discussed.

7.1.2 What does valency changing devices do

By definition, surface and deep S, A and O coincide in canonical clauses. Valence changing of course changes the surface ones, and by definition, the deep ones are not changed. What is changed is also *not* alignment: alignment is decided by the structure of the language in question and in some cases TAME categories and clause types. Speaking of alignments, external arguments may be extracted out of the *vP* to higher positions, for example: the most famous example is the subject, and if certain locational arguments are generated inside the *vP* but are understood as adjuncts in the surface-oriented analysis, then they are also moved to functional projections in TP or even CP. The basic components of these mechanisms are highly stable cross-linguistically: there are variations on how they combine (and hence various types of ergativity, for example), but they are not altered by the valency changing device. What's changed is the argument structure, and the new argument structure is fed into the largely invariable alignment procedure to create the clause we can actually see.

Still, (slightly) new A-bar positions – or the surface argument roles in other words – are created in valency changing devices. The English *by* phrase in passive clauses is unable for most types of extractions, for example, which is quite different from ordinary peripheral arguments. Claims like "in passive clauses, A becomes E" is thus just approximately correct.

There are several ways to change the argument structure. It's possible that a layer of functional projection in the canonical clause is "peeled away", or maybe added or replaced. The argument structure in a canonical clause may not strictly appear in a clause with valency changing, though with transformational analysis, relations between arguments in the two clauses can still be established. The subject in an English passive clause is uncontroversially the deep O: it's introduced in SpecTransP. However, DoP projection as in the canonical clause doesn't exist in the English passive clause: it's replaced by another version of DoP with selects a *by* phrase

indicating the agent (we say the A argument is somehow suppressed),¹⁹ and it only appears together with the participle affixation. Therefore, the deep A argument – which is introduced in the SpecDoP position – strictly doesn’t exist in the English passive clause. Still, there is a strong one-to-one mapping between the two DoPs, so we still say there is a deep A argument in the passive clause.

It’s also possible that something like an auxiliary verb (or its affixation equivalence, or serial verb construction) occurs, and in this case, a new argument is introduced. This operation doesn’t really change the existing argument structure:²⁰ it just expands the latter. But in the following procedures concerning alignment, there will definitely be some change in the mapping between deep argument labels and the A-positions. The auxiliary verb may be the spellout of features in the *vP* layer and TAME categories in the TP layer.

Valency decreasing devices have to involve at least one peeling-or-replacing-argument operation. Valency increasing devices can be (but is not necessarily) realized by the argument adding operation. It’s possible for a valency decreasing device to have auxiliary verb(s). English passivization seems like an example, though the inserted *be* is more about the TP layer and not about the argument structure. The English *get*-passivization involves a semi-auxiliary verb *get*, and the semantic role of “undergoer” or “experiencer” of the subject is definitely assigned by it, and therefore we may say *get* introduces a new argument slot, which is uncontroversially marked in the TP layer as the subject. Still, *get*-passivization involves disruption of the canonical argument structure, since it still takes a past participle expression, which is formed by replacing the original Do head to its participle version, as is described above. The so-called passivization construction in Chinese, the 被-construction, seems to lean more to the “adding auxiliary verb” side, instead of “alternating existing structure” side: when the agent is present, as in 我被他打了一顿, 他打了一顿 – a *vP* – is taken by a light verb 被 as the complement; when the agent is absent, as in 我被打了一顿, the structure is just like “I underwent beating-up”. Still, there is arguably change of the existing canonical argument structure. Suppression of the agent argument is achieved by not introducing the Do projection at the first place, but this can also be described as “first peel off the DoP projection and then insert the resulting 打了一顿我 into the 被-phrase, and then move the patient 我 to the experiencer position”. Certain degree of argument structure alternating is still present. But the derivational 我被他打了一顿 involves almost no change of the canonical argument structure.

Whenever an auxiliary verb appears, there is a problem about whether the construction is actually a serial verb construction or a complement clause construction (and the never-ending puzzle what does serial verb construction mean).

7.1.3 Applying multiple valency changing devices

The difference on whether a new light verb is introduced means there is something else that is different between English and Chinese passivization: where the A-to-E change *first* takes place. In Chinese it’s the *vP* layer, i.e. the argument structure, while in English it’s the TP layer, i.e. the alignment: after the agent argument is suppressed, only the O argument is subject to the EPP probing and get the structural nominative case. In a more surface-oriented account, we say the deep A argument in English becomes peripheral and somehow like “preposition phrase”, being indifferent about what’s going on in the rest of the clause, so the deep O argument *has to* be the surface S argument, though it’s never assigned any A-like semantic role in the argument structure, while in Chinese, the deep O argument does get some A-like semantic role in the argument structure (being the “experiencer”).

This shows a large deficiency of the deep v.s. surface argument notation, because since we can only guarantee that the surface argument labels are about A-positions, it’s in principle not possible to fully describe what’s going on when several valency changing devices are applied one by one (as in Jacques (2021, Fig. 11.1)), because the so-called surface argument labels may be simply not about argument structure, while the valency changing devices at least partially work

¹⁹The NP in the *by* phrase already gets its case, and therefore is invisible for any following probe-goal mechanism: we may say it has received an inherent case. This may be seen as a demonstration that it’s indeed a peripheral argument, because nominative and accusative cases are all structural, assigned in a much more non-local manner.

²⁰The term *existing* here (and henceforth) hints the new argument structure is obtained by applying a transformation rule on the canonical argument structure. This is, in modern perspectives, not the case, but is still a useful tool.

on the argument structure. Fortunately, for the same reason, if a language relies heavily on the alignment process to complete valency changing, then it tends to avoid too much operations on the argument structure, just as is the case in English, where semantically valency changing devices are nothing more than complement clause constructions, like the so-called “causative” *let it be done*, where a full passive clause – instead of a bare argument structure – is embedded into an argument slot of a “causative” verb. Valency changing in these languages are therefore rightfully called **voice**. For languages in which valency changing is mainly inside the argument structure, successive application of real valency changing devices which work on the argument structure instead of the full clause is permitted. Some authors still use the term *voice* (Jacques, 2021), but this of course created confusion on the typological information of the language in question.

7.1.4 Working procedure

Surface S, A and O are to be investigated based on the same set of grammatical relations that define the clause subject, clause constituent order, the interpretation scope, distribution in non-finite clauses, etc. The deep S, A and O are defined by binding, serial verb construction, etc., and also largely by semantic intuition – though without knowing the cultural background, mistakes can be done here. Consider the example of English *Jack marries Marry and Marry marries Jack* and the Chinese 她爸妈把她嫁给了他, where an asymmetry arises between 娶 and 嫁 and for 嫁 the family of the bride is the agent. So what we are actually doing here is to first investigate deep S, A and O, and then clause-level constructions, which are used to define surface S, A and O, and finally to determine whether a seemingly non-canonical construction is really a valence changing construction or something else.

When making crosslinguistic comparison, note that the naming of surface argument labels is assigned according to their correspondences with deep arguments in canonical clauses. The surface A argument in one language can be quite different from the surface A argument in another language. A word order typology with parameters defined according to the clause constituent order and the S, A, O, etc. labels (deep or surface) is likely to fail when the alignment changes. Comparing the constituent position of “topic-like argument” may be a better idea.

Box 7.1: Overview of valency changing

Valency changing is the mismatch between the prototypical argument structure of the head verb (deep argument labels) and the morphosyntactic markings of arguments in the actual clause (surface argument labels) which are classified according to their correlations with the canonical argument structure. There are basically two strategies for valency changing. In one strategy, valency decreasing is just to push an argument to a peripheral position and let the alignment mechanism to decide how to match surface argument positions with the rest of arguments (for example, in passivization, the deep O argument has to fill the surface subject position), and the semantic need of valency increasing (like causative) is primarily done by using complement clauses. In another strategy, the alignment process is largely trivial: passivization is done by create an “experiencer” position (which is A-like in the argument structure) and move the O argument into it, and then the trivial deep-A-to-surface-A alignment is applied. The first strategy is largely clause-based, and the second strategy is largely argument structure-based. The first strategy is usually limited in number of valency changing phenomena and compositionality, while this is not the case for the second strategy. Languages can mix the two strategies in one construction or in different constructions.

7.2 Passivization

8 TAME categories

TAME categories, or *non-spatial settings* (the name used by Dixon), are prototypical TP categories.

8.1 Categories discussed in Reichenbach's theory

What's commonly called *tense* in traditional Latin grammar actually has complex inner structures. Reichenbach proposes the earliest theory on this topic. He recognizes three points in time to define Latin (and English) "tenses". The first is the speech time (S), the time when a clause is uttered. The second is the event time (E), the time when the event corresponding to the clause happens. Note that an event may last for a certain period of time, and in this case, when is E requires a further parameter, i.e. which stage of the event is emphasized. This topic isn't discussed in detail in Reichenbach's theory, but I still place it in this section (§ 8.1.3), anyway. The third point in time is the **point of reference (R)**. It's a point in time that is somehow highly relevant to the event in question, for example, a consequence of it. While S and E are about actual events in realis clauses (§ 8.4.1), R is always conceptual.

8.1.1 Tense: the relation between S and R

The category of **tense** codes the relation between S and R. If S happens after R (we use R-S to denote this circumstance), we say it's **past tense**. If S and R happen together (we use R,S to denote this circumstance), we say it's **present tense**. S-R is the **future tense**.

8.1.2 Completion

The category of **completion** codes the relation between R and E. E-R is **perfect** or **anterior**. E,R is **simple**, and R-E is **posterior**. Completion is sometimes also called *aspect*, though this is in conflict with § 8.2.1.

As the name *completion* implies, in many languages, the event time is the moment when the event ends, and

8.1.3 Phase of activity

Now we discuss the problem about what's the event time, especially for a durative event (§ 8.2). The **phase of activity** of a clause may be beginning, continuing or finishing (BLT § 19.6).

8.2 The inner makeup of an event

8.2.1 Composition: how the inner makeup of an action is perceived

If the speaker wants to emphasize the inner makeup of an event, then the clause is **imperfective** in its **composition**; otherwise it's **perfective**. In English grammar, we do have the perfective-imperfective distinction, the latter being more commonly known as **progressive** (CGEL § 3.1 [3]). Note that the composition of a clause can be relatively independently with the actual extension of the event it describes: opening a door is almost a transient event, but we will say *I'm opening the door* when asked about what we are doing. One way to elicit a progressive clause is like the follows: *I was writing an article when he knocked the door*. Whether he knocked the door for a while isn't important here, so the *when* clause is non-progressive, while the main clause is about what was going on in a particular time step and the inner makeup of my writing the article is important here, so the progressive is used.

The composition is the most accepted meaning of the term *aspect*. But the term is also used to denote § 8.1.2,

8.2.2 Temporal extent: the real makeup of an event

The temporal extent – the really makeup of an event, not how it's perceived – may also be marked in languages. This is not the category of the English progressive v.s. non-progressive distinction: *I slept* is "non-progressive" in the English grammar tradition, but it may be punctual (at that particular time, I just went to sleep) or durative (I slept during a certain time period).

8.3 Maybe more than one single event ...

8.3.1 Frequency and degree

8.3.2 Boundedness

8.4 Whether the event really happens

When we ask whether something happens, we may be asking about whether it happens in our world or maybe just in an imaginary world (in other words, having the tendency to happen), or we may be asking about how certain *we* are about the event's happening.

8.4.1 Realis and irrealis

8.4.2 Modality

8.4.3 Evidentiality

Evidentiality is about how sure the speaker is about a clause representing an event. The speaker may just eyewitness the event. Or maybe it's just heard from somewhere else.

8.5 TAME categories in the real word

The above framework of TAME categories is an idealized one. No attested language compositionally realizes these categories. It's quite possible for a language to ignore a category, or to somehow “fuse” two categories (§ 8.5.2) to form a single category, as is the case of English or Latin “tense”.

How TAME categories are marked is also not uniform. Prototypical marking of TAME categories include verb affixation and/or auxiliary verbs. But it's of course possible to have *periphrastic* conjugation: some configurations of TAME categories are marked morphologically, while others are marked partly by auxiliary verbs (§ 4.2.3). And though adverbs, PPs, and serial verb constructions, which can be used to describe the temporal information of an event with or without TAME categories in detail, are usually optional and hence may be recognized as modifiers instead of markers of grammatical categories, adverbs like *now* never appear with past tense, and now if the past tense suffix in English gets eroded one day, there may still be arguably a tense system hidden in the distribution of temporal adverbs. This is exactly how things work in Cinque hierarchy: the habitual adverb *usually*, for example, is introduced as the specifier of Adv_{habitual}.

8.5.1 The status of future

8.5.2 Fusion of categories

8.5.3 Compatability with other categories

TAME categories are limited in clauses that are non-finite (§ 9) or headed by a somehow “stative” verb.

9 Non-finite clauses and nominalization

In generative syntax, finiteness is in a low position in the CP domain. It determines what TAME categories are possible in the TP domain: non-finite clauses are usually highly limited in TAME marking, (which may be understood as “feature inheritance” in some generative theories; I'll skip theoretical controversies around this). This even makes some authors to give up the term *non-finite* completely and use terms like *non-tense* instead (Dixon, 2005, § 2.2.1). Non-finiteness is sometimes confused with **nominalization**: *playing the national anthem* is sometimes said to be a nominal clause, indicating that it has already been nominalized. But this is not quite true: it's *playing of the national anthem* that is truly nominalization, while *playing the national anthem* marks the object like all clauses else, can be modified by adverbs, etc., so everything beside the *-ing* form of the head hints it's a clause, not an NP. Still, sometimes nominalization and non-finite clauses are similar enough: in Classical Latin, for example, so-called gerunds

almost never take objects, but they can be modified by adverbs, and this raises the question whether they are non-finite clauses or nominalizations.

10 Speech force in grammar

10.1 Clause types

11 Simple clauses

11.1 About the notion of *clause*

The term *clause* has no mutually accepted definition. Of course it must contain the verb (or the verbal adjective) and its arguments, but is that enough? What's a unit with the verb and complements but without any TAME marking (if it's possible)? And what's a unit with TAME marking but without any definite speech force? The *vP* constituent, the *TP* constituent and the *CP* constituent all possibly appear in complement positions, making it hard to define clausehood by "independence". And don't forget the split projection theory.

One terminology system, adopted in (邓思颖, 2010, pp. 140), names full *CPs* with fully marked speech force as *sentences* and *CPs* with only clause types marked as *clauses*. This terminology is peculiar to Chinese, because Chinese has a rich sentence final particle system coding speech acts much more than traditionally recognized clause types like declarative or imperative (compare § 8.3 and § 8.4 in that book – and that's why the author only assumes split *CP* but not split *TP*). In English, grammatically coded speech force is a synonym of clause type, leading some linguists to use the label *Force* to denote the functional head responsible for clause type. This is not the notation used in 邓思颖 (2010, pp. 142). The term *small clause* is used in 邓思颖 (2010) to denote verbless clauses (pp. 173), but it's used in other places more generally as an informal name of *vPs* (Chinese verbless clauses can be seen as a *vP* headed by a somehow "predicative" light verb), or a bare argument structure in more surface-oriented terms.

Coincidentally (or maybe not so coincidentally), Dixon assumes a clear distinction between clauses and sentences, although he also says what is only marked in sentences is just coded speech force (which he names as *mood*), like "imperative". But here is a subtlety: a clause like *what you want* is definitely not interrogative in its speech force, but it does have the clause type of *interrogative*, because of the existence of *what*. Thus, we may split Dixon's *mood* into a largely syntactic version, according to which *what you want* is interrogative, and a version with significance at the syntax-pragmatics interface, for which *what you want* doesn't have a definite value. We may understand the notion of *sentence* as a clause with the latter version of *mood* marked, and this brings the definition in 邓思颖 (2010) and BLT together.

Sentences are less frequently embedded than clauses. Embedded sentences are usually quoted speech, and in some writing systems may be surrounded by quotation marks.

Now the problem becomes whether a single term *clause* is enough for all syntactic objects in the surface-oriented analysis. Even in surface-oriented analyses, it's well recognized that clauses are of different sizes, which, in generative terms, means some clauses have more functional projection layers than others. The idea of Cinque hierarchy means if a grammatical category (or grammatical relation) is present in a clause, then grammatical categories and relations below it in the functional hierarchy are also highly likely to appear. If TAME categories are marked, then the argument structure should be complete. If the clause has topicalization, then it is likely to have TAME categories. Something

Clarifying the meaning of the terms is of course important for fully understanding various subordination devices, like complement clause constructions (§ 13.2) or relative constructions. Indeed, the study of the latter feeds back to the study of clausehood.

Box 11.1: Definition of *sentence*, *clause*, and *small clause*

In this note, a **sentence** means a clause plus *full* marking of speech force, while the exact meaning of a *clause* is indefinite. A full clause is an argument structure plus TAME marking and clause type marking, the last indicating certain aspects of speech force. But it's also possible to have reduced clauses, in which certain functional projections

are peeled off. A bare argument structure is named a **small clause**, and the name also applies to small clauses with only little further modification.

11.2 The verb complex

periphrastic conjugation may also be seen as a complement clause construction.

11.3 Constituent order

12 Information packaging

Information packaging, i.e. syntactic marking of the information structure (what are new, what are old, what are focused, etc.), involves several strategies. Certain non-canonical constructions within the nucleus clause, like valency changing, despite having independent functions, have marked information structure. For example, passivization naturally emphasizes what is done instead of who does it. Pre- or post-nucleus constructions, like topicalization, are frequently about information packaging.

12.1 Topicalization

For morphologically rich languages, the topic may have special morphological marking, which may even override the morphological marking of structural case received in the TP layer (like the nominative or accusative case). In this case, the marking of the topic is called the topic case.

13 Clause combining

The term *subordination* is slightly narrower than the caption of this section. To be precise, coordination (§ 14.1) and supplementation (§ 15) are also means of clause combining, but since they are not restricted to clauses, I'll discuss about them later.

13.1 Serial verb construction

13.2 Complement clause

Complement clauses can be used to replace several grammatical devices: together with verbs with secondary meanings, they replace certain TAME markings (§ 8.1.3), certain valency changing devices like the causative (§ 7.1.3),

14 Coordination

14.1 Clausal coordination

14.2 Coordination in NPs

15 Supplementation
